$$P/b = 25{,}000\,t^2/L \quad [29]; \qquad y = PL^3/7{,}500{,}000\,b\,t^3 = L^2/300\,t, \quad [30]$$

whence

$$\text{Recommended thickness} = L^2/300\,y, \quad [31]$$

where $y$ = maximum deflection, in. For a spring supported at both ends and loaded in the middle, $L = \frac{1}{2}$ (effective length between end supports); each arm carries $\frac{1}{2}$ full load.

## 6. VIBRATION IN SPRINGS

**LONGITUDINAL OR LATERAL VIBRATIONS** of helical, or lateral vibrations of flat or leaf springs carrying an attached load.—The natural frequency is given by

$$\text{Frequency} = 3.12\sqrt{k/(W_L + C_1\,W_S)} \text{ cycles per second,}$$

where $k$ = stiffness of the spring, lb. per in. of deflection; $W_S$ = weight of spring itself, and $W_L$ = weight of load carried by spring, lb.; $C_1$ = constant; for helical springs in extension or compression $C_1 = \frac{1}{3}$; for cantilever springs of uniform cross section $C_1 = \frac{1}{4}$; for semi-elliptic springs of uniform cross section with load at center, $C_1 = \frac{1}{2}$. For leaf springs the proportion of the weight of the spring which must be taken as acting with the load depends on the number of master leaves and on other variables. In a cantilever leaf spring it would be but a small proportion, possibly one-eighth.

Usually the weight of the attached load is so great, as compared to the weight of the spring, that spring weight can be ignored in the equation. The equation is inexact if the attached load equals or is less than the weight of the spring itself. Dash pots or other damping devices act to slow down this frequency slightly, but usually the change is not over 1 to 5%.

**TORSIONAL VIBRATIONS** in spiral springs or torsion helical springs.—Frequency = $1.245\sqrt{T/I}$ vibrations per second, where $T$ = stiffness of spring, in.-lb. of torque per revolution; $I$ = mass moment of inertia of the rotating body, lb.-in.$^2$, including one-third of the mass moment of inertia of the spring, in addition to the inertia of the attached mass.

**TRAVELING WAVES** moving back and forth within the helical spring itself.—Frequency = $8.85\sqrt{k/W_S}$, where $k$ and $W_S$ have the same meaning as before.

In valve springs this type of vibration has a frequency of 15,000 to 25,000 vibrations per min. If frequency is an exact multiple of operating speed, resonance may occur. In work done both in the U. S. and Great Britain, resonances have been found up to as high as the 25th harmonic. Maximum effects usually occur below the 12th harmonic. This spring surge usually is accompanied by poor valve seating, resulting in noise and loss of power. It also has caused many valve spring breakages, the fracture usually occurring at between one and two coils from the end of the spring. The exact shape of the cam greatly influences the magnitude of these waves for any given harmonic. Re-design of the spring, change of cam contour, or change of weight of valve mechanism may be necessary to overcome the difficulty.

## 7. ENDURANCE OF SPRINGS

Extensive research has been made on the endurance of springs and spring steels under repeated stress. Fatigue tests of hot-rolled spring steel (Grade 5), tested in a cycle of torsional stress between zero and a maximum, resulted in the following indications: The endurance limit, or maximum stress at which steel will withstand the test indefinitely, is close to the proportional limit in torsion, *viz.*, about 85,000 lb. per sq. in. Preliminary results from fatigue tests on full-size railroad type helical springs suggest that a somewhat lower fiber stress, possibly 75,000 lb. per sq. in. (with the Röver correction) more accurately represents the endurance limit when in spring form. Further tests are needed to confirm or disprove this tentative result.

In standard fatigue tests in bending, stress usually is completely reversed; *i.e.*, the cycle is between positive and negative stresses of the same numerical value. The endurance limit for Grade 5 steel under these conditions is about 100,000 lb. per sq. in. The ultimate strength of this steel, heat treated to a troostitic condition, is about 190,000 lb. per sq. in. According to the Goodman diagram the endurance limit for a zero-maximum-stress cycle would be about 130,000 lb. per sq. in. Therefore, an elliptic spring in which the maximum stress never exceeds the latter figure should last indefinitely. It is difficult accurately to apply the criterion to an actual case. In practical manufacturing, unavoidable departures from the ideal spring of theory occur, which may give rise to serious local variations in maximum stress, notably in the short plates.

It is well known that surface defects, such as pits, seams, guide marks, decarburization, etc., even if slight, have a marked effect on endurance limit. This is particularly true of the comparatively thin sections used in elliptics. Ground and polished specimens show endurance limits very much higher than those from an ordinary hot-rolled finish.

In large hot-coiled springs, surface defects probably are not as important as in an elliptic spring; conversely, they are harder to control. A helical spring cannot be ground or polished economically after coiling; the best that can be done is to use centerless ground and polished bars, and guard carefully against decarburization throughout the subsequent operations of fabrication and heat treatment.

## 8. COMPARATIVE EFFICIENCY OF SPRINGS

The primary function of a spring is to store energy, and later return it when needed. The efficiency of different types of springs, therefore, may be compared on the basis of the amounts of energy which they will store per cubic inch or per pound of metal in the spring. Conversely, the potential energy storage per cubic inch of metal in a given type of spring may be used to estimate the volume or weight of spring needed to perform a given task.

**THE MODULUS OF RESILIENCE,** or amount of energy that may be stored in 1 cu. in. of metal in a spring, is given by the equations

$$M_r = S^2/mG \text{ or } M_r = S^2/mE \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; . \quad [32]$$

where $M_r$ = modulus of resilience; $S$ = allowable unit stress, lb. per sq. in.; $G$ = modulus of elasticity in shear; $E$ = modulus of elasticity in tension or compression. For values of $G$ and $E$ see Table 1. Values of $m$ for different types of springs are as follows:

| Shape of Spring | Relative Efficiency | $m$ | |
|---|---|---|---|
| Helical spring, extension or compression service, round wire | 50% | 4 | A |
| Square wire | 30.8% | 6.5 | |
| Straight wire used in tension | 100% | 2 | B |
| Helical spring used in torsion, round wire | 25% | 8 | |
| Square or rectangular wire | 33% | 6 | |
| Spiral power spring, round wire | 25% | 8 | |
| Flat wire | 33% | 6 | |
| Leaf spring | up to 33% | 6+ | |
| Flat spring, uniform cross section, concentrated load | 8 1/3% | 24 | |

A—Metal in shear; Modulus of Resilience = $S^2/mG$
B—Metal in tension; Modulus of Resilience = $S^2/mE$

If correction factor for curvature $k$ is to be included

$$M_r = S^2/k^2mG \text{ or } M_r = S^2/k^2mE \quad . \; . \; . \; . \; . \; . \; . \; . \quad [33]$$

For values of $k$, see pages 10–06 and 10–15.

To find the volume of active metal needed in any spring, multiply the maximum deflection by 1/2 the maximum load, and divide by the modulus of resilience for that type of spring. The result should be increased by 5 to 10% or more, to allow for the inactive or partly inactive metal in end coils or loops. By introducing a proper correction factor results can be obtained in terms of weight of spring, rather than in terms of cubic inches of material.

Examples.—1. Music wire compression spring to show maximum compression of 0.5 in. under a load of 10 lb. Unit stress, 80,000 lb. per sq. in. *Solution.*—Here $m = 4$ and $G = 12{,}000{,}000$.

$M_r$ = (80,000 × 80,000)/(4 × 12,000,000) = 133 in.-lb. per cu. in. Volume of metal needed = 0.5 × 5/133 = 0.0188 cu. in. per spring, or 0.020 cu. in. after a reasonable allowance for inactive material has been added. At 0.284 lb. per cu. in. for steel, the springs will weigh 5.68 lb. per thousand.

2. Steel torsion helical spring to develop torque of 100 in.-lb. for an angle of twist of 2 revolutions. Use round wire and unit stress of 120,000 lb. per sq. in.

*Solution.*—$M_r$ = (120,000 × 120,000)/(8 × 30,000,000) = 60 in.-lb. per cu. in. Angle of twist in radians = $4\pi$. Volume of active metal needed = $4\pi \times 50/60$ = 10.46 cu. in. net, or 11 cu. in. allowing for inactive metal. Weight per spring = 11 × 0.284 = 3.12 lb.

In each of these cases many alternative designs using different wire and coil diameters are possible, but for all of these designs the comparative efficiency is about the same. Approximately the same net weight of material will be required. The following, however, should be noted:

1. It is often commercially advisable to use stock sizes of wire, and round dimensions for coil diameter, even if these sizes result in lowered unit stresses and greater weight of metal. 2. The efficiency factors tabulated above assume the springs to be properly detailed at the ends. If load is improperly applied, the spring may be severely over-stressed locally, compelling reductions in working loads, and, hence, in the energy-storing capacity of the spring. 3. Judgment must be exercised in estimating the percentage to be allowed for inactive metal.

## AXLES AND SHAFTS

### 1. AXLES

(See also Shafting, p. 24–03)

The terms, axle, shaft and spindle, are applied to rotating or oscillating machine parts whose motion is constrained by journals or bearings. Such members may be classified according to the predominating stress, or according to the particular purpose for which they are used as: *a*. Axles, loaded transversely and subject principally to bending, as axles of railroad cars. *b*. Shafts subjected to torsion or to combined torsion and bending, as transmission shafting or the shafts of engines. *c*. Spindles, or short shafts which carry a tool for actually doing work or which carry the work itself, and in consequence must have accurate motion. Examples are shafts or spindles of machine tools.

**MATERIALS OF AXLES AND SHAFTS.**—Bessemer steel, open-hearth steel and alloy steel are commonly used. While Bessemer steel is extensively used, open-hearth steel usually is specified for shafts for armatures and engines, and for machine tool spindles and shafts operating under similar conditions. Alloy steel is used where great strength is required. Nickel-steel, because of its ability to withstand heavy shocks and torsional stresses, is well adapted for axles and shafts. See pp. 2–21 and 2–40 for specifications of suitable steels.

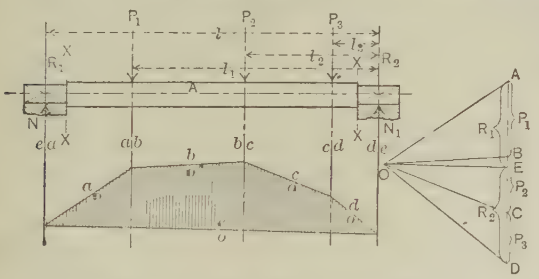

Fig. 1. Bending Moment of a Shaft

**AXLE DESIGN.**—The graphical method is best adapted to the solution of axle problems, as it gives the moments at all sections, and shows at once the location of the *maximum* bending moment. Fig. 1 shows a typical case.

Axle *A* carries the loads $P_1$, $P_2$, $P_3$. Torsional moment due to friction is neglected. The axle is considered as supported at the center of the bearings $N$ and $N_1$. The dangerous section, unless the shaft is very short, will be where the bending moment is a maximum.

In Fig. 1, denote the forces $P_1$, $P_2$, etc., as *ab*, *bc*, *cd*, etc., and draw the corresponding force diagram as shown, making $AB = P_1$, $BC = P_2$, $CD = P_3$ to any convenient scale. These forces are drawn consecutively downward, as they act in that direction; their sum *AD*, must equal the sum of the reactions, or vertical forces. From any pole, *O* draw *OA*, *OB*, *OC*, and *OD*. From any point on *ab*, in the space diagram, draw *oa*, and *ob*, parallel respectively to *OA* and *OB* in the force diagram. From the intersection of *ob* and *bc* draw *oc*, parallel to *OC*, and similarly draw *od*. Join the intersection of *oa* and *ea* with the intersection of *od* and *de*, thus locating the closing string *oe*. Draw *OE* parallel to *oe*, locating *E*. Then in the force diagram $DE = R_2$, $EA = R_1$ to the assumed scale of the force diagram.

The vertical ordinates of the space polygon are proportional to the bending moments at the point considered. The numerical value of any bending moment is the continued product of the length of the ordinate, the perpendicular distance of *O* from *AD*, the *reciprocal* of the scale of the space diagram, and the *reciprocal* of the scale of the force diagram. Thus, if a given ordinate is 2 in., the pole distance 2 $^1/_2$ in., the space scale 1 $^1/_2$ in. = 1 ft., or $^1/_8$ size, and 1 in. = 5000 lb. on the force diagram; then the bending moment at the point considered, $M = 2 \times 2\,^1/_2 \times 8 \times 5000 = 200{,}000$ in.-lb. From this moment the diameter of the shaft may be computed.

If the shaft is short, resulting in a small section to withstand the applied bending moment, the section at $XX$ should be checked for shearing. Also it is important that all forces acting be considered, and that the maximum value of each be selected. It has been found (Machine Design, Smith and Marx) that the force due to vertical oscillation caused by jar in running is about 40% of the static load for car axles. Hence, the axle should be designed for 1.4 × the static load. In addition, there is in car axles, a bending moment due to curves, switches, and wind pressures. This may amount, at a maximum, to the equivalent of a horizontal force, of 40% of the static load, applied at a height of 6 ft. from the rail. Also, due to the reversal of stress, which causes the fibers to be subjected alternately to tension and compression, the allowable unit stress is correspondingly reduced. For data on standard locomotive and tender axles see Kent's Mechanical Engineers' Handbook—Power, pp. 14–25 to 14–27, forming Vol. 2 of this series.

## 2. SHAFTS

The American Standards Assoc. has issued a code for the design of transmission shafting, in which all of the commonly used theories are discussed, and a rational procedure for the design of shafts under all conditions of loading is developed. The following notes are abstracted from the code:

**Notation.**—$A$ = area of cross-section, sq. in.; $\alpha$ = ratio of maximum to average intensity of stress, resulting from axial loading only; $D$ = outside diameter of shaft, in.; $d$ = inside diameter of hollow shaft, in.; $E$ = modulus of elasticity, approximately 30,000,000; $F$ = axial tensile or compressive load, lb.; $K = d/D$ = ratio of inside diameter to outside diameter of hollow shafts; $K_m$ = shock and fatigue factor to be applied to the computed bending moment; $K_t$ = shock and fatigue factor to be applied to the computed torsional moment; $k$ = radius of gyration of transverse cross-section of the shaft, in.; $l$ = length of shaft between centers of supports, in.; $M$ = maximum bending moment, in.-lb.; $N$ = rev. per min.; $P$ = maximum power transmitted by the shaft, horsepower; $p_t$ = maximum intensity of shearing stress in shaft, lb. per sq. in. = 8000 for commercial shafting without allowance for keyways = 6000 with allowance for keyways *; $S$ = maximum flexural stress, either tension or compression, lb. per sq. in. = 16,000 for commercial shafting without allowance for keyways = 12,000 with allowance for keyways *; $S_s$ = maximum torsional shearing stress, lb. per sq. in. = 8000 for commercial shafting without allowance for keyways = 6000 with allowance for keyways *; $T$ = maximum torsional moment, in.-lb.; $V$ = transverse shear, lb.; $W$ = transverse load supported by shaft, lb.

SOLID SHAFTS.—The formulas recommended differ from the formulas heretofore in general use in that they introduce factors $K_m$ and $K_t$ for shock and fatigue. These factors vary with the nature of the load. Values are given in Table 1.

**Shafts in Pure Torsion.**—

$$K_t\,T = 0.1963\,S_s\,D^3 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [1]$$

$$D = \sqrt[3]{321{,}000\,K_t\,P/S_s\,N} \quad . \quad . \quad . \quad . \quad . \quad . \quad [2]$$

**Shafts Subjected to Bending.**—

$$D = \sqrt[3]{32 K_m\,M/\pi\,S} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [3]$$

**Shafts Subjected to Combined Torsion and Bending.**—

$$D = \sqrt[3]{(16/\pi\,p_t)\sqrt{(K_m\,M)^2 + (K_t\,T)^2}} \quad . \quad . \quad . \quad . \quad [4]$$

If the diameter to transmit a given horsepower is desired, it may be found by substituting for the term $(K_t\,T)^2$ in equation [4] its value in terms of horsepower, as follows:

$$(K_t\,T)^2 = (396{,}000\,K_t\,P/2\pi\,N)^2 \quad . \quad . \quad . \quad . \quad . \quad [5]$$

**Shafts Subjected to Torsion, Flexure and Axial Loading.**—This is the general case, and all other shaft formulas may be derived from it by the omission of the factors that do not apply to the case under consideration.

$$D = \sqrt[3]{\frac{16}{\pi p_t}\sqrt{\left(K_m\,M + \frac{\alpha\,F\,D\,(1 + K^2)}{8}\right)^2 + (K_t\,T)^2}} \times \frac{1}{\sqrt[3]{1 - K^4}} \quad . \quad . \quad [6]$$

To determine the diameter of a shaft in terms of horsepower transmitted, substitute in equation [6] the value of $(K_t\,T)^2$ as found by equation [5].

**Shafts in Bending over Short Spans with Heavy Transverse Shear.**—

$$D = \sqrt{16\,V/3\,\pi\,S_s} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [7]$$

---

* $S$ may be taken as 60% of the elastic limit in tension, but not more than 36% of the ultimate tensile strength of steel purchased under definite physical specifications. Similar values for $S_s$ and $p_t$ are 30% of elastic limit and 18% of ultimate strength.

**Table 1.—Shock and Fatigue Factors for Shafts**

| | $K_m$ | $K_t$ |
|---|---|---|
| **Stationary Shafts** | | |
| Gradually applied loads | 1.0 | 1.0 |
| Suddenly applied loads | 1.5–2.0 | 1.5–2.0 |
| **Rotating Shafts** | | |
| Gradually applied or steady loads | 1.5 | 1.0 |
| Suddenly applied loads, minor shocks only | 1.5–2.0 | 1.0–1.5 |
| Suddenly applied loads, heavy shocks | 2.0–3.0 | 1.5–3.0 |

**Shafts Subjected to Combined Torsion and Heavy Transverse Shear.—**

$$p_t = (16\,T/\pi\,D^3) + (16\,V/3\,\pi\,D^2) \quad . \; . \; . \; . \; . \; . \; . \quad [8]$$

**Diagrams for Solution of Shafting Problems.**—All of the equations given above except equations [7] and [8] can best be solved by the diagrams Figs. 2 and 3. In these diagrams, the heavy arcs represent standard transmission shafting sizes, and the lighter arcs the standard machinery shafting sizes. The scale of abscissas represents values of $K_m\,T$; the scale of ordinates at the right represents values of $K_t\,T$; the scale of ordinates at the left represents the values of $K_t\,P$, where $P$ = horsepower at 100 r.p.m. The diagrams are applicable to steady, fluctuating, reversing, and gradually or suddenly applied loads, with or without minor or heavy shocks, provided that correct values of $K_m$ and $K_t$ are used. They are not applicable to shafts in bending over short spans with heavy transverse shear, or to shafts subjected to combined torsion and heavy transverse shear.

The diagrams are based on a maximum permissible shearing stress of 6000 lb. per sq. in., but can be used for other stresses by multiplying the shaft diameter found from the diagram by an appropriate factor as follows:

| | | | | | | |
|---|---|---|---|---|---|---|
| Shearing stress, lb. per sq. in. | 4000 | 5000 | 6000 | 7000 | 8000 | 9000 |
| Factor | 1.14 | 1.06 | 1.00 | 0.95 | 0.91 | 0.87 |

EXAMPLE 1.—Required the size of shaft to withstand a maximum bending moment $M$ of 9350 lb., and a maximum torsional stress $T$ of 9600 lb., the allowable unit shearing stress being 8000 lb. per sq. in., and the load suddenly applied with minor shock. From Table 1, values of $K_m$ and $K_t$ may be taken as 1.5 and 1.25 respectively. Then $K_m\,M = 1.5 \times 9350 = 13{,}975$ and $K_t\,T = 9600 \times 1.25 = 12{,}000$. In Fig. 2, the intersection of $K_m\,M = 13{,}975$, and of $K_t\,T = 12{,}000$ lies on the arc representing a shaft 2 $1/2$ in. diameter, with a unit stress of $p_t$ of 6000 lb. per sq. in. Since the allowable unit torsional stress in the present case is 8000 lb., the correct diameter for the conditions given is found by applying the factor for the higher stress. $2.5 \times 0.91 = 2.275$. The next higher standard size of shaft is 2 $5/16$ in.

EXAMPLE 2.—Required the size of an alloy steel shaft to transmit 210 Hp. at 150 r.p.m., and at the same time sustain a bending moment of 90,000 in.-lb. The unit allowable shearing stress may be taken as 9000 lb. per sq. in. At 150 r.p.m., 210 Hp. is equivalent to $210 \times (100/150) = 140$ Hp. at 100 r.p.m. The intersection of 140 Hp. and $K_m\,M = 90{,}000$ in Fig. 3 shows that a shaft 4 $3/4$ in. diameter would be required at a unit shearing stress of 6000 lb. per sq. in. Applying the factor 0.87 for the higher unit stress, $4.75 \times 0.87 = 4.1325$ in. The next larger standard shaft is 4 $1/4$ in. diameter.

EXAMPLE 3.—Required the size of a non-rotating shaft to support a steady load of 4000 lb., the supports being spaced 3 ft. apart. From the equation for simple beams (see p. 7–22), $M = Wl/4 = 4000 \times (3 \times 12)/4 = 48{,}000$ in.-lb. From Table 1, $K_m = 1$ and $K_m M = 48{,}000$. Since there is no rotation $T = 0$, and $K_t\,T = 0$. In Fig. 3, on the abscissa of $K_t\,T = 0$, at a value of $K_m\,M = 48{,}000$, the nearest size of shaft that will be suitable at a unit shearing stress of 6000 lb. per sq. in., is 3 $1/2$ in.

**HOLLOW SHAFTS.**—All of the foregoing equations are applicable to hollow shafts, when multiplied by a factor equivalent to $(1/\sqrt[3]{1 - K^4})$, in which $K = d/D$, that is, the ratio of the inside and outside diameters. Values of $(1/\sqrt[3]{1 - K^4})$ are as follows:

| | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| $K$ | 0.95 | 0.90 | 0.85 | 0.80 | 0.75 | 0.70 | 0.65 | 0.60 | 0.55 | 0.50 |
| $\sqrt[3]{1 - K^4}$ | 0.57 | 0.70 | 0.78 | 0.84 | 0.88 | 0.91 | 0.93 | 0.95 | 0.97 | 0.98 |
| $1/\sqrt[3]{1 - K^4}$ | 1.75 | 1.43 | 1.28 | 1.19 | 1.14 | 1.10 | 1.07 | 1.05 | 1.03 | 1.02 |

The procedure is to determine the diameter of a solid shaft for the given conditions, and to then multiply the diameter so found by the factor corresponding to the desired value of $d/D$.

EXAMPLE 4.—Determine the size of a hollow shaft to be used under the conditions given in Example 1, assuming the value of $K$ to 0.70. As determined in Example 1, the diameter of a solid shaft required would be 2.275 in. The factor for $K = 0.70$ is 1.10. Therefore the outside diameter of an equivalent hollow shaft would be $2.275 \times 1.10 = 2.250$ in. The inside diameter would be $2.25 \times 0.70 = 1.75$ in.

**SHAFTS UNDER AXIAL LOADING.**—The maximum intensity of stress resulting from a force $F$ applied axially is $S = \alpha\,F/A$, where $\alpha$ = ratio of maximum to average

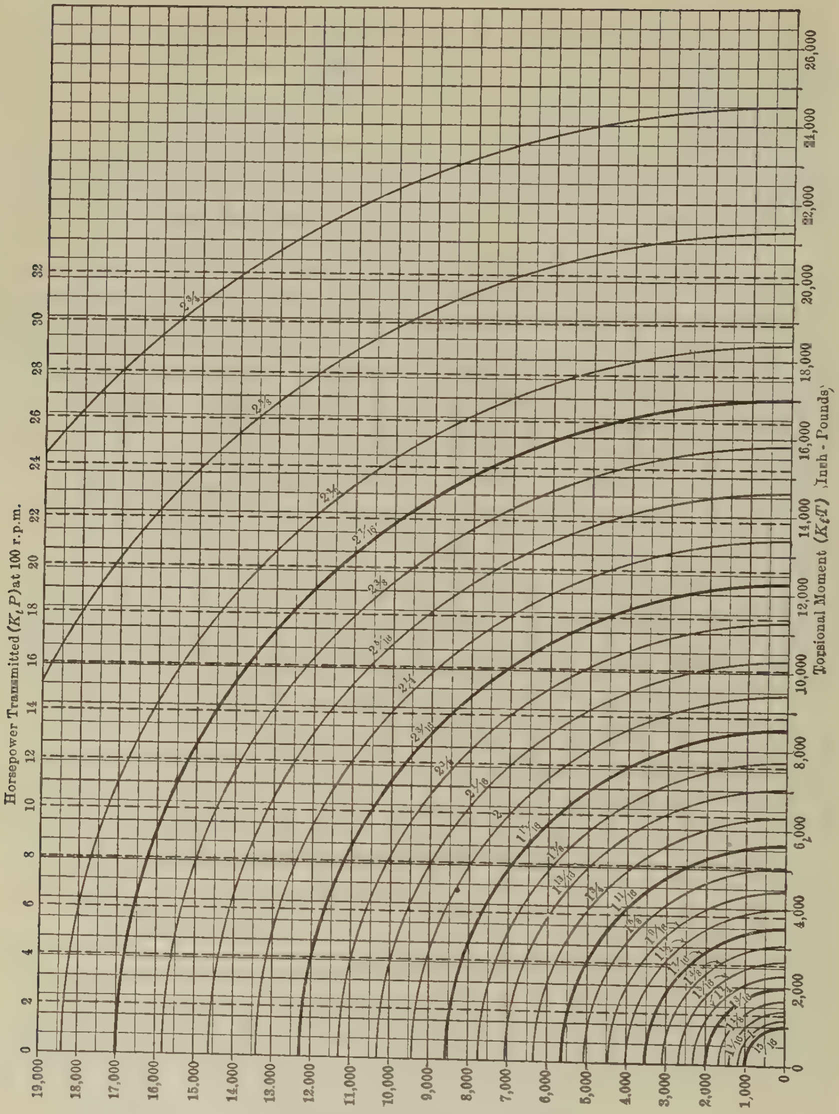

Fig. 2. Shaft Selection Chart

intensity of stress resulting from the axial load only, and $A$ = cross-sectional area of the shaft, sq. in. If the shaft is rigidly supported at short intervals and virtually acts as a column under compressive loads, $\alpha = 1$. Under all tensile axial loads $\alpha$ also is 1. If the shaft is not rigidly supported, it acts as a long column, and $\alpha$ should be computed by one of the long column formulas. Values of $\alpha$, for ratios of $l/k$ up to 115, computed according to the formula

$$\alpha = 1/\{1 - 0.0044\ (l/k)\} \qquad [9]$$

are given below. For ratios of $l/k$ greater than 115, use Euler's equation (see p 7–35).

| | | | | | | |
|---|---|---|---|---|---|---|
| Ratio $l/k$ .................. | 0 | 25 | 50 | 75 | 100 | 115 |
| $\alpha$ ......................... | 1.00 | 1.12 | 1.28 | 1.49 | 1.78 | 2.02 |

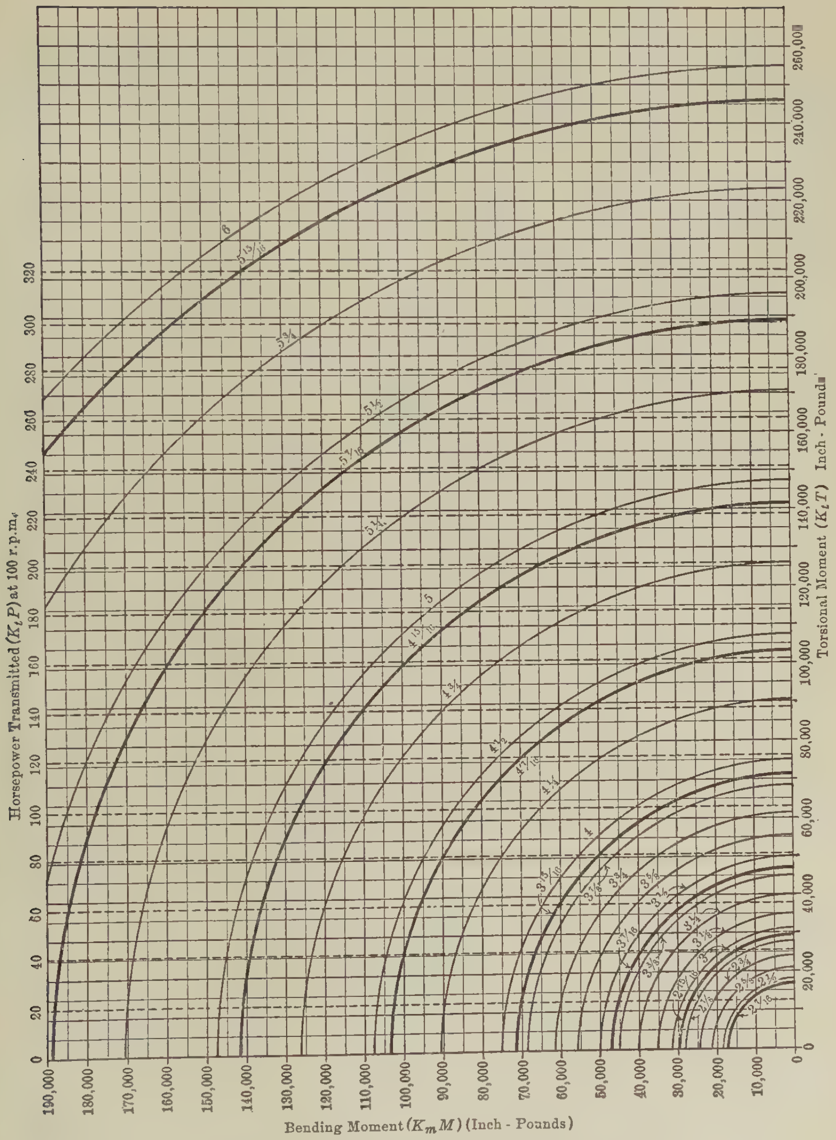

FIG. 3. Shaft Selection Chart

The value of $\alpha$ so determined then should be used in equation [6] to determine the size of shaft requied.

**SHAFTS UNDER ALTERNATING STRESS.**—Shafts subjected to torsion and bending encounter reversal of stress at each revolution, and should be calculated by means of equation [4]. The value to be ascribed to the shock and fatigue factors, $K_t$ and $K_m$, which take into account the stress reversals, depend on the conditions under which the shaft operates. No general statement can be made concerning the values to be used, since the shock factor, in particular, depends on the resiliency of the shaft system as a whole. For complete stress reversal $K_t$ and $K_m$ should be 1.5.

## Table 2.—Critical Speed Equations

NOTATION.—$N_1$, $N_2$, $N_3$ = critical speeds, r.p.m.; $\Delta_1$ $\Delta_2$ = static defection, in., at $W_1$ and $W_2$ (shaft horizontal); $d$ = diam. of shaft, in.; $I$ = moment of inertia; $E$ = 29,000,000. Weights taken in pounds; vertical shafts considered as horizontal.

| | | |
|---|---|---|
| Single Concentrated Load | General Formula: $N_1 = \frac{187.7}{\sqrt{\Delta_1}}$. | [10] |
|  | $N_1 = 187.7\sqrt{\frac{1}{\Delta_1}} = 387{,}000\frac{d^2}{ab}\sqrt{\frac{l}{W_1}};\ \Delta_1 = \frac{W_1 a^2 b^2}{3EIl}$. | [11] |
|  | $N_1 = 1{,}550{,}500\, d^2\sqrt{\frac{1}{W_1 l^3}} = 187.7\sqrt{\frac{1}{\Delta_1}};\ \Delta_1 = \frac{W_1 l^3}{48EI}$. | [12] |

## 3. CRITICAL SPEED OF SHAFTS

The center of mass of a rotating shaft never lies in its mechanical axis of rotation; hence, in a horizontal or inclined shaft, even if additional loads are neglected, there is a deflection caused by the weight of the shaft itself, which causes the center of mass to lie below the true axis of rotation. When rotation begins the shaft remains bent downward, but as the speed increases the centrifugal force increases until a state of equilibrium is established at what is called the critical speed. At this speed the centrifugal force is just sufficient to counteract the force tending to deflect the shaft downward, and the shaft rotates in a bowed form, and it is said to be in a "whirl." As vertical shafts cannot be in perfect balance the same applies to them. At the critical speed the maximum vibration of the revolving mass, and consequently of its support, occur, and for this reason, determination of critical speed is of prime importance in design. Above the critical speed the center of mass revolves inside the bow of the shaft, the tendency being to cause the rotating mass to revolve about its own center of gravity and not about the mechanical axis. This condition is met by providing special bearings which will accommodate themselves to the conditions, or by providing a flexible shaft which is just strong enough to withstand the deflection stresses in passing through the critical speed.

This refers to the first or lowest critical speed, $N_1$. There is a series of secondary critical speeds, $N$, of higher value with diminishing amplitudes of vibration. See paper by S. H. Weaver in *Trans.* A.S.M.E., 1910, from which Table 2, p. 11–08, is taken.

In addition to the equations in Table 2, equation [30] (E. A. Lof, *Machy.*, Feb., 1909) is useful for a multiple-loaded shaft,

$$N_1 = \frac{N_a N_b N_c}{\sqrt{N_b^2 N_c^2 + N_c^2 N_a^2 + N_a^2 N_b^2}} \quad . \; . \; . \; . \; . \; . \; . \quad [30]$$

where $N_1$ = first critical speed of the system, $N_a$ = first critical speed of unloaded shaft, $N_b$, $N_c$ = first critical speed of each separate load.

## CRANKS AND CRANK-PINS

**OVERHUNG CRANKS.**—Works on machine design give the proportions shown in Figs. 1 and 2 for cast-iron and forged steel cranks. While the drawings show different methods of securing the pin to the crank, the best practice is to use either press or shrink fits, both for the pin and for attaching the crank to the shaft.

Let $F$ = greatest load on the crank-pin, when crank and connecting-rod are at right angles; $S$ = maximum allowable stress in the crank, lb. per sq. in.; $L$ = distance from center of pin to section at which stress is to be computed, in. Then dimensions may be checked for bending action at any section, as C-D, Fig. 2, by the following equations:

$$\text{Bending Moment} = FL = t\,W^2\,S/6 \quad . \; . \; . \; . \; . \; . \; . \quad [1]$$

$$t = 6\,FL/W^2 S \quad . \; . \; . \quad [2]; \quad W = \sqrt{6\,FL/t\,S} \quad . \; . \; . \; . \; . \; . \quad [3]$$

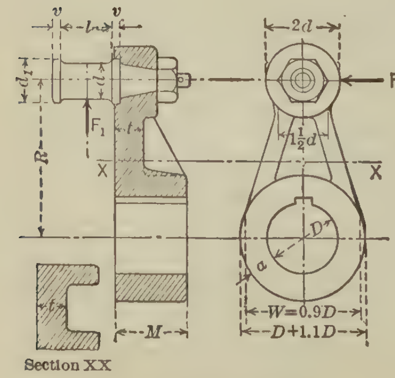

Fig. 1. Cast-iron Crank

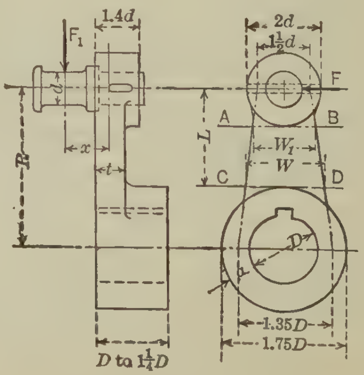

Fig. 2. Forged Steel Crank

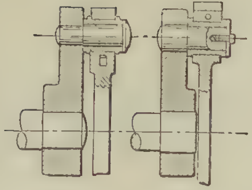

FIG. 3 FIG. 4
Methods of Reducing Crank Overhang

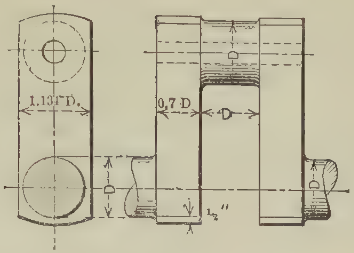

FIG. 5. Forged Crank-shaft

For cast-iron cranks $t$ may be taken as 0.6 $D$. The diameter of the crank-pin bosses $d_1$ may be taken as $d_1 = 1.16\,d + 0.02$ in. to $1.24\,d + 0.02$ in. The thickness of the bosses, $v$, may be taken as $0.75\,(d_1 - d)$.

Let $F_1$ = greatest force acting on the crank-pin when the crank is on dead centers. The bending moment at the section A–B, Fig. 2, then is

$$F_1\,x = W_1\,t^2\,S/6 \qquad [4]$$

$$W_1 = 6\,F_1\,x/t^2\,S \qquad [5]; \qquad t = \sqrt{6F_1\,x/W_1\,S} \qquad [6]$$

For steel cranks, $S$ may be taken as 4500 to 5500 lb. per sq. in.

The thickness of metal in the hub or boss of the crank (dimension $a$, Fig. 1), varies with the length of the boss. Values of $a$ given by Seaton are as follows, $D$ being the diameter of the crank-shaft:

| $M$ = | 1.0 $D$ | 0.9 $D$ | 0.8 $D$ | 0.7 $D$ |
|---|---|---|---|---|
| $a$, iron = | 0.35 $D$ | 0.38 $D$ | 0.40 $D$ | 0.41 $D$ |
| $a$, steel = | 0.30 $D$ | 0.32 $D$ | 0.33 $D$ | 0.34 $D$ |

**FORGED CRANK-SHAFTS.**—Low and Bevis (Manual of Machine Drawing and Design) give the dimensions shown in Fig. 5, based on a large number of examples chiefly taken from marine practice. Sometimes a hole $^1/_3$ the diameter of the pin is drilled through the crank-pin as shown.

**CRANK-DISCS,** Fig. 6, are often used in small engines which run at high speed. The weight $W$, opposite the crank-pin is for the purpose of balancing the crank-pin, and the part of the connecting-rod which revolves with it. The following proportions may be used in designing crank-discs: $D_1 = D$ to $1.2\,D$; $B = 0.7\,D$ to $D$; $A = 0.9\,B$; $C = 0.25\,D$; $E = 0.4\,D$; $F = 2d$; $H = d$ to $1.5\,d$; $L = B$ to $1.25\,B$.

**BALANCED CRANKS.**—Fig. 7 shows a method of balancing cranks. When the size of the weight is determined by experiment the counterweight must be detachable as shown in Fig. 8. Fig. 9 shows a case where the center of mass of the balance weight does not fall opposite the crank-pin.

**STRENGTH AND PROPORTIONS OF OVERHUNG CRANK-PINS,** Fig. 10.—The dimensions of crank-pins are based on the strength required to resist all the forces to which it will be subjected, and on the intensity of pressure permissible between pin and journal. This pressure must be kept low enough to avoid forcing lubricant out of the bearing, in which event heating and excessive wear would occur. Bending action on the pin is $^1/_2\,F\,L$, where $F$ = load on the pin, lb., and $L$ = length of pin, in. If $S$ = allowable maximum stress, lb. per sq. in., and $d$ = diameter of pin, in., the resisting moment $M_r$, in.-lb., is $M_r = \pi\,d^3\,S/32$. Hence

$$FL = d^3\,S/5.1 \qquad [7]$$

and

$$d = 1.721\,\sqrt[3]{F\,L/S} \qquad [8]$$

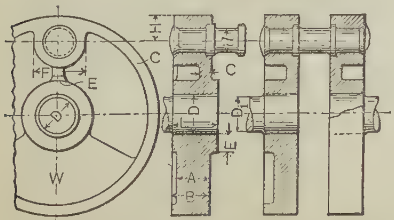

FIG. 6. Crank-discs

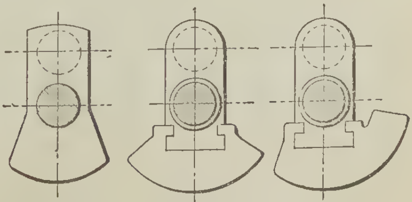

FIG. 7 FIG. 8 FIG. 9
Methods of Balancing Cranks

The stress in the pin is alternately compression and tension. The value of $S$, therefore should be taken as not over 5500 for steel. With this value of $S$, for a given ratio of $L/d = J$, equation [8] becomes

$$d = \sqrt[4]{J\,F/107.9} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [9]$$

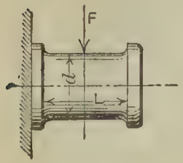

FIG. 10. Crank-pin

To avoid heating, pins usually are made of greater dimensions than are called for by equation [9]. Heating depends on the bearing pressure, which in turn depends on the projected area of the bearing, that is, on $d \times L$. If $P$ be the bearing pressure, lb. per sq. in., $F = P\,L\,d$, and $L = F/P\,d$. Substituting this value in equation [8], we have

$$d = \sqrt[4]{5.1\,F^2/PS} \quad . \quad . \quad . \quad . \quad . \quad . \quad [10]$$

or, for a value of $S = 5500$,

$$d = \sqrt[4]{F^2/107.9\,P} \quad . \quad . \quad . \quad . \quad . \quad . \quad [11]$$

For data on allowable bearing pressures see pp. 13–31 to 13–33.

**FORCES ACTING ON CRANKS.—Tangential Forces.**—In engines, if the center-line of the crank-shaft lies in the same plane as center of the piston and crosshead, the effective force of the crank acts in a line tangent to the crank circle at any given position of the crank. This effective force is

$$F_t = P \sec \beta \sin (\beta + \alpha) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [12]$$

where $F_t$ = effective tangential force on the crank-pin, lb.; $P$ = total force acting on the

**Table 1.—Factors for Determining Tangential Effort**

Factor = $\sec \beta \sin (\beta + \alpha)$

Forward stroke is toward crank-shaft. Velocity of crosshead = velocity of crank-pin × tabular value

piston, lb. = area of piston, sq. in. × pressure on piston, lb. per sq. in.; $\alpha$ = angle between crank and the line between center of crank and center of piston; $\beta$ = angle between connecting-rod and the line between center of crank and center of piston. Table 1 gives values of sec $\beta$ sin($\beta + \alpha$) for various ratios of $l/r$, where $l$ = length of connecting-rod, in., and $r$ = radius of crank, in. If the crank is used to impart motion to a crosshead, as in a punch press, the resistance encountered by the crosshead, *i.e.*, the resistance of the metal to shearing or deformation, is taken as the value of $P$. The tangential force to be applied to the crank then can be computed, from which the horsepower required is determined. Force acting along the center line of the connecting-rod is

$$F_c = \frac{P}{\cos\beta} \qquad [13]$$

The force acting on the guides is

$$F_g = P \tan\beta \qquad [14]$$

Notation as before.

**Inertia Forces.**—The velocity of the crosshead or piston at a given position of the crank, when center line of piston and crank-shaft are in the same plane, is, approximately

$$V_p = V_c\,(\sin\alpha + r \sin 2\alpha/2\,l) \qquad [15]$$

where $V_p$, $V_c$ = respectively, velocity of piston and crank-pin, ft. per sec.; other notation as before.

The acceleration of the reciprocating parts is

$$a = V_c^2\,(\cos\alpha \pm r\cos 2\alpha/l)r \qquad [16]$$

and the inertia forces, lb. per sq. in. of piston, is

$$F_i = (WV_c^2/g)\,(\cos\alpha \pm r\cos 2\alpha/l)/Ar \qquad [17]$$

In these equations $a$ = linear acceleration, ft. per sec. per sec.; $W$ = total weight of

**Table 2.—Inertia Factors**

Values of $\cos\alpha \pm (r/l)\cos 2\alpha$. Algebraic signs relate to forward stroke; use opposite signs for return stroke

| Crank Angle, Forward Stroke, deg. | Ratio (Length of connecting-rod/length of crank) | | | | | | | | | | | Crank Angle, Return Stroke, deg. |

reciprocating parts, lb.; $A$ = area of piston, sq. in.; $r$ = crank radius, ft.; $g$ = acceleration due to gravity = 32.2. Table 2, p. 11–13, gives values of $(\cos\alpha \pm r\cos 2\alpha/l)$ for various ratios of $l/r$.

**POSITION OF PISTON OR CROSSHEAD FOR VARIOUS CRANK ANGLES** is given in Table 3 for various ratios of $l/r$. If $L_p$ = distance of piston or crosshead from the dead center position, at any given crank angle,

$$L_p = r\,(1 - \cos\alpha \pm r^2\sin^2\alpha/2l), \text{ approx.} \quad \ldots\ldots \quad [18]$$

If the center line of motion of the reciprocating parts is not in the same plane as the center line of the crank-shafts, but is at a perpendicular distance $d$ away from it, the stroke is greater than $2r$, and the dead centers are not symmetrical. In this case the length of stroke is

$$S = \sqrt{(1+r)^2 - d^2} - \sqrt{(1-r)^2 - d^2} \quad \ldots\ldots \quad [19]$$

**Graphical Determination of Velocity and Acceleration of Reciprocating Parts.**— Fig. 11 shows a graphical method of determining the velocity and acceleration of the piston or crosshead at any given position of the crank. This method is known as the Klein construction. From the center $A$ of the crank, draw $AC$ to a scale representing the linear velocity of the crank-pin, at the desired angle to the line $AE$ joining the center line of the crank and crosshead. With $C$ as the center and $AC$ as the radius, describe a circle. Draw the connecting-rod $CE$ to the same scale as $AC$ and describe on it a circle of diameter $CE$. Draw the chord $FG$ between the intersection of the two circles, intersecting $AE$ at $D$. At $A$, erect a perpendicular to $AE$ intersecting the prolongation of $CE$ at $B$. Then the length $AD$ represents the acceleration of the crosshead and the length $AB$ the velocity of the crosshead at the position of the crank as drawn.

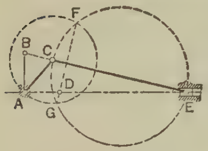

Fig. 11. Graphical Determination of Velocity and Acceleration

**Table 3.—Piston Positions for Various Crank Angles**

From beginning of stroke toward crank-shaft. Distance of piston from beginning of stroke = tabular value × length of stroke.

# FLY-WHEELS

## 1. ENERGY OF FLY-WHEELS

**FLUCTUATIONS OF ENERGY.**—The function of a fly-wheel is to store up and to restore the periodic fluctuations of energy given to or taken from an engine or machine, and thus to keep approximately constant the velocity of rotation. The quantity $\Delta E/2E_0$ is the coefficient of the fluctuation of speed or of unsteadiness, where $E_0$ = mean actual energy, and $\Delta E$ = excess of energy received or of work performed, above the mean, during a given interval. The ratio of the periodical excess or deficiency of energy $\Delta E$ to the whole energy exerted in one period ranges in single-cylinder engines worked expansively, from $^1/_6$ to $^1/_4$; the shorter the cut-off the higher the value. For a pair of engines with cranks at 90 deg. the value of the ratio is about $^1/_4$ its value for single-cylinder engines; for three engines with cranks at 120 deg., $^1/_{12}$ its value for single-cylinder engines. For tools working at intervals, such as punching, slotting, shearing, and forging machines, $\Delta E$ is nearly equal to the whole work performed at each operation. A fly-wheel reduces the coefficient $\Delta E/2E_0$ to a fixed amount, which is about $^1/_{32}$ for ordinary machinery, and $^1/_{50}$ or $^1/_{60}$ for machinery for fine purposes.

If $b$ = reciprocal of the intended value of the coefficient of fluctuation of speed, $\Delta E$ = fluctuation of energy, $I$ = moment of inertia of the fly-wheel alone, $a_0$ = its mean angular velocity, and $g$ = acceleration due to gravity = 32.2,

$$I = b\,g\,\Delta E/a_0^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [1]$$

As the rim of a fly-wheel usually is heavy in comparison to the arms, $I$ may be taken as equal to $W\,r^2$, where $W$ = weight of rim, lb. and $r$ = radius of wheel. Then

$$W = b\,g\,\Delta E/a_0^2\,r^2 = b\,g\,\Delta E/v^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [2]$$

where $v$ = velocity of the rim, ft. per sec. The usual mean radius of the fly-wheel in steam engines is from 3 to 5 times the length of the crank. Ordinary values of the product $b\,g$, the unit of time being 1 second, lie between 1000 and 2000. Values of $b$ are given in Table 1.

**ENERGY OF FLY-WHEELS IN INTERMITTENT WORK.**—The method developed by O. S. Beyer (*Am. Mach.*, Oct. 17, 24, 1912) assumes that the weight of the rim of the fly-wheel is 68.6% and that of the hub and arm, 31.4% of the total weight of the wheel. These percentages were found to be practically constant in a large number of fly-wheels examined. Table 2 gives the velocity, ft. per sec., at 1 r.p.m. of the center of gyration and of the rim, for the cross-sections of rim shown in Fig. 1, with different diameters of fly-wheels. The velocity factor in the table multiplied by the r.p.m. of the wheel gives the actual velocity. Energy of the wheel then can be determined from the formula

$$E = {}^1/_2\,(Wv_1^2/g) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [3]$$

where $E$ = energy, ft.-lb., $W$ = weight, lb., $v_1$ = velocity of radius of gyration, ft. per sec. Energy also can be determined from Fig. 2 when the value on the energy scale corresponding to the given velocity is multiplied by the total weight in pounds of the fly-wheel.

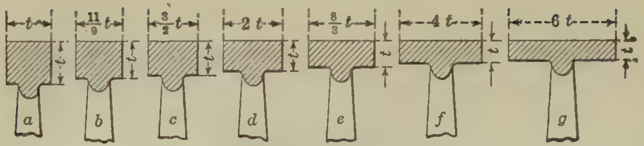

FIG. 1. Fly-wheel Rim Cross-sections

Fig. 3 gives relation between loss of velocity in a fly-wheel and energy expended. Fig. 4 shows the relation of total and expended energy to loss of velocity. By means of Table 2 and these three curves practically all problems relating to fly-wheels on intermittent work may be solved.

EXAMPLE 1.—Find the energy in a cast-iron fly-wheel 60 in. outside diameter with a rim 6 × 6 in. of cross-section *a*, Fig. 1, running at 100 r.p.m. *Solution.*—Taking weight of cast iron as 0.26 lb. per cu. in., weight of the rim, representing 68% of total weight of wheel, is

$$(60 - 6) \times 3.1416 \times 6 \times 6 \times 0.26 = 1588 \text{ lb.}$$

The wheel complete weighs 1588 ′0.686 = 2315 lb. From Table 2 the velocity of radius of gyration for a 60-in. wheel is 0.2029 ft. per sec. at 1 r.p.m., or 20.29 ft. per sec. at 100 r.p.m. The energy in the wheel is

$$E = \tfrac{1}{2}(Wv_1^2/g) = \tfrac{1}{2}\{(2315 \times 20.29^2)/32.2\} = 14{,}800 \text{ ft.-lb.}$$

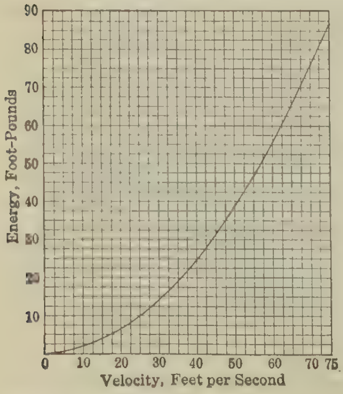

FIG. 2. Relation of Energy and Velocity

The same result may be obtained by finding in Fig. 2 the energy corresponding to 20.29 ft. per sec. to be 6.40 ft.-lb., whence 2315 × 6.40 = 14,816 ft.-lb.

EXAMPLE 2.—What energy will be expended by the wheel in Example 1 if the velocity is reduced to 85 r.p.m.? *Solution.*—Reduction in velocity is (100–85) = 15 r.p.m. = 15%. Below the point on the curve corresponding to a diminution of velocity of 15% read the percentage of energy expended as 28. The total energy in the wheel at 100 r.p.m. being 14,800 ft.-lb., the energy expended by reducing the speed to 85 r.p.m. will be 14,800 × 0.28 = 4144 ft.-lb.

Fig. 4 gives information as to the energy that may be expended when the diminution of velocity is to be kept within certain limits, and also the diminution of velocity that will occur when the energy expenditure is limited to a certain percentage of the total energy.

EXAMPLE 3.—What energy must be contained in a fly-wheel that must deliver up to 500 ft.-lb. during each cycle with a diminution of speed not to exceed 8%?

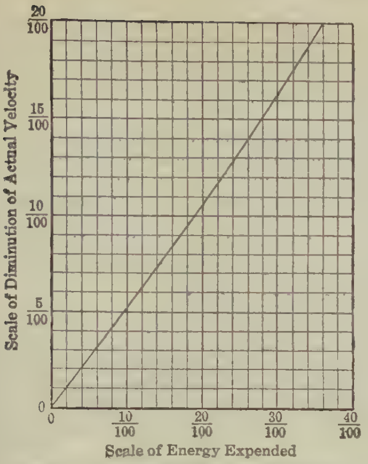

FIG. 3. Relation of Energy Expended and Velocity

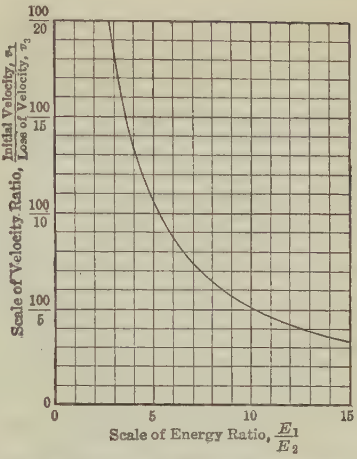

FIG. 4. Relation of Energy Expended and Diminution of Velocity

*Solution.*—Below the point on the curve, Fig. 4, corresponding to the ratio $v_1/v_3 = 100/8$, read on the scale of energy ratio $E_1$ $E_2$ the quantity 6.5. This is the ratio of total energy of the wheel to expended energy. Hence, the total energy in the wheel will be $6.5 \times 500 = 3250$ ft.-lb.

EXAMPLE 4.—Required the normal velocity of a fly-wheel that is to expend a maximum of $33^1/_3$% of its total energy, with a minimum speed of 65 r.p.m. Then $v_1$ = normal velocity, $v_2$ = minimum velocity = 65 r.p.m., and $v_3$ is the loss of velocity = $(v_1 - v_2)$. $E_1$ = energy in the wheel at velocity $v_1$, and $E_2$ = energy expended. Then $E_1/E_2 = 100/33^1/_3 = 3$. *Solution.*—Opposite the point on the curve, Fig. 4, corresponding to $E_1/E_2 = 3$ find 100/18 on scale of $v_1/v_3$. Then $v_1/v_3 = 100/18$, and $v_3 = 0.18\ v_1$. $v_3 = (v_1 - v_2) = (v_1 - 65)$, whence $0.18\ v_1 = (v_1 - 65)$, and $v_1 = 79.2$ r.p.m.

**STRESSES IN FLY-WHEELS.**—Let $W$ = weight of rim, lb. $D$ = diameter of wheel, ft. $R$ = mean radius of rim, ft. $N$ = rev. per min. $V$ = velocity of rim, ft. per min. $v$ = velocity of rim, ft. per sec. = $2\,\pi\,R\,N/60$. $g$ = acceleration due to gravity = 32.2. Then centrifugal force of whole rim is

$$F = Wv^2/gR = 4\,W\pi^2\,RN^2/3600\,g = 0.000\,341\,WRN^2 \quad . \quad . \quad . \quad . \quad [4]$$

The resultant of half the centrifugal force acting at right angles to a diameter tends to disrupt one-half of the wheel from the other half. It is resisted by the section of the rim at each end of the diameter. The ratio of the resultant of half the radial forces, taken at right angles to the diameter, to the sum of the radial forces is $1/(1/2\pi) = 2/\pi$. Hence the force tending to rupture the fly-wheel is

$$F_1 = (F/2) \times (2/\pi) = (0.000341\,WRN^2/2) \times (2/\pi) = 0.000\,108\,54\,WRN^2 \quad . \quad [5]$$

Since the force is resisted by the section at each end of the diameter the stress $S$ at any cross-section of the rim is $^1/_2$ of this, and $S = 0.000\,054\,27\,W\,R\,N^2$. The weight $W_1$ of a rim of cast iron of 1 sq. in. cross-section is $2\pi\,R \times 3.125 = 19{,}635\,R$ lb., whence stress, lb. per sq. in. of cross-sectional area of rim, is

$$S_1 = 0.001\,065\,6\,R^2\,N^2 = 0.000\,266\,4\,D^2\,N^2 = 0.000\,027\,V^2 \quad . \quad . \quad . \quad . \quad [6]$$

For wrought iron

$$S_1 = 0.001\,136\,6\,R^2\,N^2 = 0.000\,284\,2\,D^2\,N^2 = 0.000\,028\,8\,V^2$$

For steel,

$$S_1 = 0.001\,159\,3\,R^2\,N^2 = 0.000\,290\,1\,D^2\,N^2 = 0.000\,029\,4\,V^2$$

For wood,

$$S_1 = 0.000\,088\,8\,R^2\,N^2 = 0.000\,022\,2\,D^2\,N^2 = 0.\,000\,002\,25\,V^2$$

The specific gravity of wood is taken as 0.6 = 37.5 lb. per cu. ft. or $^1/_{12}$ the weight of cast iron.

## 2. WEIGHT OF FLY-WHEELS

**WEIGHT OF FLY-WHEELS FOR ENGINES.**—The weight of a fly-wheel for a given engine can be determined by means of equation [2]. The determination of $\Delta E$, however, involves a tedious graphical analysis of the performance of the engine from the probable indicator card in order to ascertain the excess or deficiency of energy at various points of the stroke. Various empirical equations of the form $W = C \times \text{Hp.}/N^2\,D^2$ have been devised to determine the weight without this analysis. Several of these are given in Table 3. In the application of the equations, the weight of the hub and arms should be subtracted from the total weight of the wheel. While in large wheels the weight of these parts may amount to from 30 to 35% of the total weight, their fly-wheel effect is only 7 to 10% of that of the rim.

**FLY-WHEELS FOR PRESSES, PUNCHES, SHEARS, ETC.**—The function of the fly-wheel on punching and similar machinery, in which action is intermittent, is to store up energy during the portion of the stroke when no work is being done and to deliver it during the period of actual working. The delivery of energy is accompanied by a reduction in the velocity of the fly-wheel.

**Notation.**—$E$ = total energy in the wheel at maximum velocity, ft.-lb. $E_1$ = energy delivered by the wheel during speed reduction, ft.-lb. $v_1$ = initial velocity of center of

### Table 3.—Equations for Weight of Fly-wheels

**Notation.**—$W$ = weight of fly-wheel rim, lb. $A$ = area of cylinders, sq. in. $s$ = length of stroke, in. $S$ = length of stroke, ft. $p$ = mean steam pressure, lb. per sq. in. $K$ = variation of speed, percent of mean speed. $D$ = diameter of fly-wheel, ft. $N$ = rev. per min. I.Hp. = indicated horsepower of engine. $d$ = diam. of engine cylinder, in. $j$ = a coefficient, values given in Table 3. $b$ = coefficient of steadiness, values given in Table 1. $C$ = constant. $V$ = mean velocity of fly-wheel rim, ft. per sec.

NOTE.—$p$ denotes compression to initial steam pressure; $0.7p$ denotes compression to 0.7 × initial steam pressure; 0 denotes no compression.

* Mean values. † Values useful for comparison; fly-wheels dimensioned from these values probably would be so light as to be structurally weak.

gravity of fly-wheel rim, ft. per sec. $v_2$ = velocity of center of gravity of fly-wheel rim, at end of period during which energy is delivered. Hp. = horsepower required. $N$ = strokes of press or shear per min. $T$ = time required for stroke, sec. $t$ = time required for actual cutting of metal per stroke, sec. $W$ = weight of fly-wheel rim, lb. $d$ = diameter of rim at center of gravity. $R$ = r.p.m. of fly-wheel at initial velocity. $a$ = width of fly-wheel rim, in. $h$ = depth of fly-wheel rim, in. $y$ = ratio of depth to width of rim. $g$ = acceleration due to gravity = 32.2. $c$, and $c_1$ = constants whose values are as follows:

| Percent speed reduction = | 2 1/2 | 5 | 7 1/2 | 10 | 15 | 20 |
|---|---|---|---|---|---|---|
| $c$ = | 0.000 002 13 | .000 004 26 | .000 006 17 | .000 008 10 | .000 011 80 | .000 015 35 |
| $c_1$ = | 0.1250 | .0625 | .0432 | .0328 | .0225 | .0173 |

$$E = Wv_1^2/2g = Wv_1^2/64.4 \qquad [13]$$

$$E_1 = W(v_1^2 - v_2^2)/64.4 \qquad [14]$$

$$W = (E_1 \times 64.4)/(v_1^2 - v_2^2) \qquad [15]$$

$$v = 2\pi RN/60 \qquad [16]$$

A simplified method of calculating fly-wheels for punches and shears is given in *Machinery's Handbook*, page 316. Using the above notation,

$$\text{Hp.} = EN/33{,}000 = E/(T \times 550) \qquad [17]$$

$$E_1 = E\{1 - (t/T)\} \qquad [18]$$

$$W = E_1/cD^2R^2 \qquad [19]$$

$$a = \sqrt{1.22\,W/12\,Dy} \qquad [20]$$

$$h = ay \qquad [21]$$

For cast-iron fly-wheels with maximum stresses of 1000 lb. per sq. in., $W = c_1 E_1$; $R = 1940/D$.

Wilfred Lewis shows (*Trans.* A.S.M.E., vii, p. 549, 1886) that in belt-driven machines the belt will run off the pulley when slip exceeds 20% of the belt speed. This is the limiting low velocity, $v_2$, and for belt-driven punches and shears gives a limiting condition of

$$W = 180\,(E/v_1^2) \qquad [22]$$

**FLY-WHEELS FOR AIR COMPRESSORS.**—H. R. Goss and H. V. Putnam in *Trans.* A.S.M.E. APM-51-12, 1929, present an analysis of the determination of fly-wheels for air compressors. The paper is highly mathematical and presents curves from which the energy of the fly-wheel can be determined. Lack of space precludes presentation of the curves and formulas and the reader is referred to the original reference.

## 3. SAFE SPEEDS OF FLY-WHEELS

**DIAMETERS OF FLY-WHEELS FOR VARIOUS SPEEDS.**—If 6000 ft. per minute be the maximum rim velocity allowable, then $6000 = \pi RD$, where $R$ = rev. per min. and $D$ = diameter of wheel, ft., whence $D = 6000 \div \pi R = 1910 \div R$.

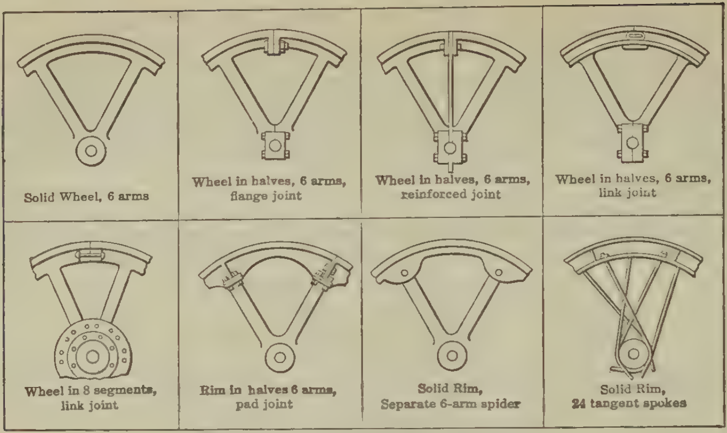
W. H. Boehm (*Eng. News*, Oct. 2, 1902), says: For a given material there is a definite speed at which rupture will occur, regardless of the amount of material used. This is expressed by

$$V = 1.6\sqrt{S/W}, \qquad [23]$$

where $V$ = rim velocity of wheel, ft. per sec. at which rupture will occur; $W$ = weight of 1 cu. in. of the material used; $S$ = tensile strength of 1 sq. in. of the material.

For cast-iron wheels made in one piece, assuming 10,000 lb. per sq. in. as the strength of large castings, and applying a factor of safety of 10, $V = 1.6\sqrt{1000/0.26} = 100$ ft. per sec. for the safe speed. For cast steel of 60,000 lb. per sq. in., $V = 1.6\sqrt{6000 \div 0.28} = 233$ ft. per sec. This is for wheels made in one piece. If the wheel is made in halves, or sections, the efficiency of the rim joint must be taken into consideration. For belt wheels with flanged and bolted rim joints located between the arms, the joints average only one-fifth the strength of the rim, and no such joint can be designed having a strength greater than one-fourth the strength of the rim. If the rim is thick enough to allow the joint to be reinforced by steel links shrunk on, as in heavy balance wheels, one-third the strength of the rim may be obtained in the joint. This construction cannot be applied to belt wheels with thin rims.

Table 5 is given by Mr. Boehm (*Am. Mach.*, Nov. 17, 1904) as the safe revolutions per minute of cast-iron wheels of different diameters. If $s$ = strength of a wheel with no joint, the strength of the various types of joint is: Flange joint, $0.25\,s$; pad joint, $0.50\,s$;



Solid Wheel, 6 arms

Wheel in halves, 6 arms, flange joint

Wheel in halves, 6 arms, reinforced joint

Wheel in halves, 6 arms, link joint

Wheel in 8 segments, link joint

Rim in halves 6 arms, pad joint

Solid Rim, Separate 6-arm spider

Solid Rim, 24 tangent spokes

Fig. 5. Types of Fly-wheel Joints

link joint, 0.60 *s*. The construction of these various types of joint is shown in Fig. 5. The table is based on a margin of safety on speed of approximately 3, which is equivalent to a margin on stress developed, or factor of safety in the usual sense of 9. The table assumes the solid wheel to have an efficiency of construction *e* of unity, whereas Prof. Benjamin's tests (see below) give it an efficiency of only 0.85. The table probably overestimates the strength of the wheels.

**Wooden Wheels.**—For hard maple, having a tensile strength of 10,500 lb. per sq. in., and weighing 0.0283 lb. per cu. in., we have, using a factor of safety of 20, and remembering that the strength is reduced one-half because the wheel is built up of segments, $V = 1.6\sqrt{262.5 \div 0.0283} = 154$ ft. per sec. The stress in a wheel varies as the square of the speed, and the factor of safety on speed is the square root of the factor of safety on strength.

**DESTRUCTIVE SPEEDS OF FLY-WHEELS.**—Various types of fly-wheel construction (see Fig. 5) were tested to destruction by Prof. C. H. Benjamin (*Trans.* A.S.M.E., xx, p. 209, 1899, xxiii, p. 168, 1902), by revolving them in a bomb-proof casing. The speed was increased gradually until the wheel burst. The averages of the results of the experiments are given in Table 6. From two to four wheels of each type were tested, except Type 5, of which only one wheel was tested.

## 4. DIMENSIONS AND CONSTRUCTION OF FLY-WHEELS

**THICKNESS OF RIM.**—F. A. Halsey (Handbook for Machine Designers) gives the following equations for rim velocity at which bursting of the fly-wheel may be expected. Let $v$ = bursting velocity of rim, ft. per sec.; $t$ = tensile strength of material, lb. per sq. in.; $w$ = weight of material, lb. per cu. in.; $e$ = efficiency of construction, values being given in Table 6.

Then

$$v = 1.64 \sqrt{(t\,e/w)} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [24]$$

For cast iron with $w = 0.26$ and $t = 19{,}000$, $v = 443 \sqrt{e}$.

For steel, with $w = 0.28$ and $t = 60{,}000$, $v = 757 \sqrt{e}$.

These equations should be used with caution in designing fly-wheels, as stresses exist in the rim other than simple tension due to centrifugal force. The arms restrain the free expansion of the rim, with the result that the free section of the rim between arms acts as a uniformly-loaded beam, the load being due to the centrifugal force of the material in the section. The stress due to this action is to be added to the simple tension stress, and the resulting stress is always greater than that given by the equations. This beam action is exceptionally serious in built-up wheels with joints between the arms, the joint being equivalent to a joint in the middle of a beam and not to a simple splice in a tension member. The beam action may be reduced by increasing the number of arms, and the fiber stress due to beam action, other things being equal, is inversely as the square of the number of arms.

An equation for the thickness of rim based on the number of arms is given by J. B. Standwood in *Trans.* A.S.M.E., xiv, p. 251, 1893. Let $T$ = thickness of rim, in.; $d$ = wheel diameter, in.; $A$ = number of arms; $v$ = rim velocity, ft. per sec.; $F$ = greatest stress, lb. per sq. in. to which any fiber is subjected. Then

$$T = 0.475\, d/A^2 \{(F/d) - 0.1\} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [25]$$

If $F$ is taken as 6000 lb. per sq. in. the following values of $T$ are found for solid rim wheels:

| | | | | | |
|---|---|---|---|---|---|
| Diameter of wheel, in. | 24 | 24 | 48 | 108 | 108 |
| Rim velocity, ft. per sec. | 50 | 88 | 88 | 184 | 184 |
| " " ft. per min. | 3,000 | 5,280 | 5,280 | 11,040 | 11,040 |
| No. of arms | 6 | 6 | 6 | 16 | 36 |
| Thickness of rim, in. | 2/10 | 15/32 | 15/16 | 2 1/2 | 1/2 |

If the limiting velocity be assumed at 88 ft. per sec. (1 mile per min.), with $F = 6000$, equation [25] becomes

$$T = 0.475\, d/0.67\, A^2 = 0.7\, d/A^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [26]$$

If the wheels are made in halves or sections, the bending strain must be taken into account and $T$ will be greater than given above. For a joint half-way between the arms, equation [25] becomes

$$T = 0.712\, d/A^2 \{(F/v^2) - 0.1\} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [27]$$

With a maximum rim velocity of 88 ft. per sec., and $F = 6000$ $T = 1.05\, d/A^2$.

**ARMS OF FLY-WHEELS AND PULLEYS.**—Equations for the arms of wheels cast in one piece can be at best only approximations, as the shrinkage stresses introduce an uncertain factor.

Prof. Torrey (*Am. Mach.*, July 30, 1891) gives for arms of elliptical cross-section

$$b = WL \div 30\, d^2, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [28]$$

where $b$ = breadth (minor axis of ellipse) of arm at hub, in.; $L$ = length of arm, ft.; $W$ = load acting on one arm, lb., and $d$ = depth of arm at hub, in. (major axis of ellipse). The value of $W$ is given by $W = Sw/n$, where $S$ = stress on belt, lb. per in. of width; $w$ = width of belt, in., and $n$ = number of arms. The formula is based on a factor of safety of 10. In using it, a value is assumed for $d$ and the value of $b$ calculated. If the resulting cross-section is too round, a larger value of $d$ is taken and $b$ is recalculated. More than two trials are seldom necessary.

Unwin gives:

$$d = 0.6337 \sqrt[3]{BD/n} \text{ for single belts,} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [29]$$

$$d = 0.798 \sqrt[3]{BD/n} \text{ for double belts,} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [30]$$

where $D$ = diam. of wheel, in. and $B$ = breadth of the rim, in., other notation as before. These formulas are based on an elliptical section of arm in which $b = 0.4\, d$ or $d = 2.5\, b$, on a width of belt = 4/5 the width of the wheel rim, a maximum driving force transmitted by the belt of 56 lb. per inch of width for a single belt and 112 lb. for a double belt, and a safe working stress of cast iron of 2250 lb. per square inch.

Using in Torrey's formula, the same value of $d$ as found by Unwin's formula for a given set of conditions, the value of $b$ is approximately only one-half that given by Unwin; that is, the arm is but one-half as strong.

F. A. Halsey (*Am. Mach.*, April 23, 1896) gives

$$x = {}^{7}/_{8}\text{ in.} + 0.04\,d + 0.153\,c, \text{ and } y = {}^{1}/_{2}\,x, \quad . \quad . \quad . \quad . \quad . \quad [31]$$

where $x$ = depth of arm and $y$ = breadth of arm, $d$ = outside diameter of rim, $c = \sqrt{a \times b}$, $a$ and $b$ being the thickness and width of rim, respectively; $b = {}^{2}/_{3}\,a$. All dimensions are in inches. Halsey recommends a rectangular cross-section with its greatest dimension radial. The formulas provide for other sections by considering all sections of the same area as equivalents and taking the side of a square of equal area as the base of the factor for the section.

The arms should taper both in breadth and depth from the hub to the rim. Halsey recommends a taper on each side of the center line of $^{1}/_{8}$ to $^{3}/_{16}$ in. per ft. in breadth and $^{1}/_{4}$ to $^{3}/_{8}$ in. per ft. in depth, depending on the size of the hub. Torrey gives a thickness at the rim of $^{2}/_{3}$ the breadth and depth at the hub. The Halsey and Unwin formulas for size of arms give results which agree well with ordinary practice.

A simple rule for the proportions of arms is given in *Machinery's Handbook* which makes the width of the arm at the hub equal to 1.3 × shaft diameter for a wheel with six arms, and 1.2 × shaft diameter for a wheel with eight arms. The minimum cross-section at the rim is two-thirds the area at the hub. The strength of the arms should be at least three-quarters of the strength of the shaft in torsion.

**Hollow Arms.**—Hollow arms may be desirable in large fly-wheels. The design procedure is first to design the wheel with solid arms and then determine the equivalent cored section. Assume an arm of elliptical cross-section in which the major axis is 2 $B$ and the minor axis is $B$; the major axis of the cored section is 2 $b$ and the minor axis is $b$. Let $t$ be the thickness of the equivalent solid elliptical arm at the hub, and 2 $t$ be its width at the hub. Then by equating the moduli of resistance for solid and hollow elliptical sections, the relation is established

$$t^3 = (B^4 - b^4)/B \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [32]$$

from which the dimensions of the arm and core can be calculated. A core box for an elliptical cross-section is difficult to make and is expensive. A core whose cross-section is a polygon of six sides closely approximating the outline of the ellipse will be equally satisfactory and will add but little to the weight of the arm. The cross-section of such a core can be determined by drawing lines at an angle of 60 deg. to the major axis of the core ellipse, at its extremities, to intersect the circumference of the ellipse. The points of intersection then are joined to the extremities of the minor axis to complete the polygon.

**CONSTRUCTIONAL DETAILS.**—The solid rim wheel, as shown by Prof. Benjamin's tests (see p. 11–20), is structurally the strongest. For fly-wheels built in sections, the common type of joint between the arms, *i.e.*, flanges, at the end of the joints with through bolts joining the flanges, is probably the worst construction that could be devised. (See Stresses in Fly-Wheels, p. 11–17.) Joints with an efficiency of 100% or more, that is, connections which are stronger than the rim itself, are obtained by means of links shrunk over lugs on the rim or tees sunk into the recess of the rim. Fly-wheel joints having an efficiency of over 100% are described by John Fritz (*Trans.* A.S.M.E., xx, p. 237, 1899) and by H. V. Haight (*Am. Mach.*, Feb. 28, 1907). The Haight construction is shown in Fig. 6. The rim section carrying the section necessary for the links joining the parts of the wheel, is cut away around the entire circumference of the rim. The rim proper, therefore, is continuous and is not weakened by the drilling of holes or otherwise cutting it away for the reception of fastening members. The net result is to give a rim of I-section which is better fitted to resist stresses than the ordinary shape of rim. Furthermore, by having the joints come at the ends of the arms, which are made double at the joints, as shown in Fig. 6, the rim is continuous between arms and the tendency to failure at the joint is minimized. Table 7 and Figs. 7–9 give the dimensions of shrink links and keyways for connections of this character.

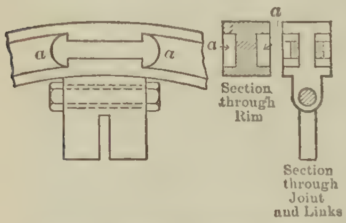

FIG. 6. Haight Fly-wheel Joint

Various designs of fly-wheel have been made for different purposes. In one type of engine fly-wheel, the rim section is cast integral with the arms. The rim section is divided into two parts on a plane perpendicular to the axis of the wheel, each part having its own set of arms. The hub is cast separately and the two halves of the rim section and the hub are fastened together by through bolts through the rim and the hub. Another type, for

a rim speed of 15,000 ft. per min., has been built with a rim formed of laminated plates. A cast-steel spider with 12 double arms had dovetail notches cut in its periphery. The laminated plates, cut in arcs of 30 deg., were machined on the inside circumference to fit the notches on the spider, and assembled with broken joints. Side cover plates, machined with a groove into which the edge of the spider rim fits, were then placed outside of the laminated plates, and the entire assembly bolted together with 10 turned and fitted through bolts in each pair of side plates. The wheel was 13 ft. outside diameter, 2 ft. 2 in. face, and weighed about 100,000 lb.

Band saw fly-wheels usually run at rim velocities of 10,000 ft. per min. and may at times run even higher. The Allis-Chalmers Co. uses a construction in which the rim is of V-section and the arms are arranged diagonally, passing from one side of the hub to the opposite side of the rim, alternate arms being staggered with respect to each other. Another construction, largely used in band saw wheels, uses spokes composed of steel bars, either round, or square and set diagonal to the plane of rotation of the wheel, which are cast into the wheel and hub. Two rows of spokes are used, alternate spokes extending from the central plane of the rim to the opposite sides of the hub. The rim is poured first, and after it has cooled the hub is poured. Shrinkage strains in the rim that might pull the hub out of line thus are avoided.

For descriptions and illustrations of the construction details of a great variety of fly-wheels, including the above, for many different services, see Halsey's Handbook for Machine Designers.

**WIRE-WOUND FLY-WHEELS** have been used where very high rim speeds were necessary. Fly-wheels used at the Mannesmann Tube Works in Hungary, designed for a tangential velocity of over 250 ft. per sec., consisted of a cast-iron hub to which two steel discs, 20 ft. diameter, were bolted. Around the circumference of the wheel thus formed 70 tons of No. 5 wire were wound under a tension of 50 lb. In the Mannesmann Works at Landore, Wales, such a wheel makes 240 r.p.m. corresponding to a tangential velocity of 15,080 ft. or 2.85 miles per minute.

A wire-wound fly-wheel designed by George Smith Morison of Melbourne, Victoria, Australia, was built for the mine of the Great Southern Consols Gold Mining Co. at Rutherglen, Victoria, in 1910. The wheel was the center unit of a direct-coupled motor-generator set supplying current to the two 100-Hp. motors of the mine hoisting plant. The fly-wheel comprised a cast-iron center hub, 2 ft. diam. by 10 in. face, to each cheek of which were bolted circular boiler steel plates 6 ft. 3 in. diam., and 3/4 in. thick. The plates further were bolted together about 14 in. inside of their periphery by a circular gallery of bolts over which were fitted 10 in. separator tubes. A ribbon of steel 10 in. wide, 1/16 in. thick was fitted over the bolts. On this steel flooring, 13 miles of No. 8 gage steel wire was wound under a tension of 120 lb. The wheel weighed about 5 3/4 tons, and it ran at a normal peripheral velocity of about 20,000 ft. per min.

**ROTATING DISCS.**—Fly-wheels in the form of a disc, or those in which the depth of the rim is so great as compared to the rim that they approximate a disc form, cannot be designed by the methods used for the conventional type of fly-wheel. The complete determination of the stresses requires an involved mathematical analysis, which is complicated by the lack of experimental data. Kimball and Barr (Elements of Machine Design) give the following equations for the radial and tangential stresses in a rapidly rotating plain disc: Let $R$, $r$ = respectively, outer and inner radii of disc, in.; $r_1$ = radius at any point, in.; $S_t$, $S_r$ = respectively, tangential and radial stresses at any radius $r_1$; $w$ = weight of material, lb. per cu. in.; $n$ = rev. per min.; $\lambda$ = Poisson's ratio = 0.3 for steel = 0.25 for cast iron. $C$ = a constant = 0.000 003 55. Then for a solid disc,

$$S_t = C\,w\,n^2\{(3+\lambda)R^2 - (1+3\lambda)r_1^2\} \quad [33]$$

$$S_r = C\,w\,n^2\{(3+\lambda)(R^2 - r_1^2)\} \quad [34]$$

For a disc with a hole at the center,

$$S_t = C\,w\,n^2[(3+\lambda)\{R^2 + r^2 + (R^2r^2/r_1^2)\} - (1+3\lambda)r_1^2] \quad [35]$$

$$S_r = C\,w\,n^2[(3+\lambda)\{R^2 + r^2 - (R^2r^2/r_1^2)\}] \quad [36]$$

By taking $r$ so small that $r^2$ is a negligible value, it can be shown that the tangential stress at the surface of the bore is twice that obtained by putting $r = 0$ in equation [33]. This shows that even a small hole at the center of a rotating disc will greatly increase the tangential stress in the disc.

Rotating discs in which the stresses are to be uniform at all points, as steam turbine discs, will be of varying cross-section and thicker at the hub than at the periphery. The design of such discs involves complicated mathematical analysis. For one method of analysis, as used for steam turbine discs, see Kent's Mechanical Engineers' Handbook—Power, p. 8–26, forming Vol. 2 of this series.

## KEYS

Keys are used to prevent relative movement of rotating members and the shafts or spindles on which they are mounted. They are of various forms, depending on the class of service in which they are to be used.

### 1. SUNK KEYS

The sunk key, *i.e.*, a key which is fitted in a groove or keyseat in the shaft, and which projects into a keyway in the bore of the other member, is the key in most common use. Sunk keys are made in various forms, as square, flat, tapered, etc. Square and flat keys preferably should be fitted on all four sides.

A key fitting tight on top and bottom of the keyway drives partly by friction. If fitted only on the sides of the keyway it exerts a prying action on the hub and shaft, and is subjected to severe bending and shearing stresses.

Taper keys (Fig. 4) are tapered on the upper surface only, *i.e.*, on the surface projecting into the hub. A corresponding taper is cut in the keyway in the hub. When the key is driven, hub and shaft are drawn together on the side opposite the key. A frictional resistance thus is established which tends to prevent axial movement of the hub on the shaft.

If the key is more tightly fitted at one end than at the other, or if the bore of the hub is tapering, the hub may be so drawn up that its axis is at an angle to the axis of the shaft. The Woodruff key (Fig. 5) adjusts itself to taper in the hub and thus avoids misalignment of shaft and hub.

**PROPORTIONS OF KEYS.**—A large number of formulas have been devised for the proportions of flat and square keys. The more important of them are the following, in which $W$ = width of key; $T$ = thickness of key; $L$ = length of key; $D$ = shaft diameter; all in inches. $t$ = taper, in. per ft.

*Machinery's Handbook:* $W = 1/4\,D$; $T = 1/6\,D$; $L = 1\tfrac{1}{2}\,D$ . . . . [1]

" " $W = 3/16\,D + 1/16$; $T = 1/8\,D + 1/16$; $L = 0.3\,D^2/T$. [2]

F. A. Halsey ($D$ = up to 4 in.),

$W = 1/4\,D$; $T = 5/8\,W$ to $3/8\,W$; $L = 1.5\,D$; $t = 1/8$ . . . [3]

" ($D$ = 4 to 6 in.),

$W = 1/4\,D - 1/8$; $T = 5/8\,W$ to $3/4\,W$; $L = 1.5\,D$; $t = 1/8$ . [4]

" ($D$ = over 6 in.),

$W = 1/4\,D - 1/4$; $T = 5/8\,W$ to $3/4\,W$; $L = 1.5\,D$; $t = 1/8$ . [5]

W. C. Unwin ($D$ over 6 in.), $W = 1/4\,D + 1/8$; $T = 1/8\,D + 1/8$ . . . . . . [6]

Formula [6] gives excessive dimensions for pulleys or shafts keyed to large shafts and transmitting small amounts of power. For such cases take $D = \sqrt[3]{100\ \text{Hp.}/N}$ or $D = \sqrt{PR/630}$, where Hp. = horsepower transmitted by pulley, $N$ = rev. per min., $P$ = force acting at circumference, lb., $R$ = radius of pulley, in.

Carl G. Barth developed in 1922 a formula based on mathematical reasoning which gives a more consistent relation of the key to the size of the shaft than previous formulas, and which is recommended for general use. This formula (see Fig. 1 for notation) is

$$t = 0.15\,D\,(D + 2)/(D + 1) \qquad [7]$$

This is represented graphically in Fig. 1, which shows the size of key for each size of shaft. The upper and lower curves show the limiting size of shaft for each commercial size of key. Barth's values are given in Table 7.

**Depth of Key Seats.**—The depth of a flat or square key is equally divided between the shaft and the hub. The depth to which a milling cutter is sunk into the shaft in milling a keyway is equal to one-half the depth of the key plus the height of the arc projecting above the intersection of the side of the keyway with the circumference of the shaft. This height can be calculated from the formula

$$H = R - \sqrt{R^2 - (1/2\,W)^2} \qquad [8]$$

where $R$ = radius of shaft, $H$ = height of arc and $W$ = width of key.

**FORMS OF KEYS.—Standard Stock Keys.**—The American Standards Assoc. has established standard sizes for parallel and flat stock keys, taper, square and flat stock keys, and square and flat taper gib-head stock keys. See A.S.A. Standard B17.1–1934. Dimensions of these keys are given in Tables 1 to 4.

* This height of the key is measured at the distance $W$, equal to the width of the key, from the large end.

† 4 1/2 in. length instead of 4 3/8 in.

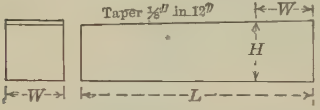

FIG. 4. Plain Taper Stock Key

the key. Dimensions of standard Woodruff keys are given in Table 5. The particular size of key to be used for various sizes of shaft may be obtained from Table 6. The dimensions of $J$, $K$, $L$ and $M$, Fig. 5, which are not given in Table 5, can be computed by means of the following formulas, in which $d$ = diameter of the shaft, other factors being as shown in Fig. 5:

Versed sine $J = \frac{1}{2} d - \sqrt{(d^2 - A^2)/4}$ . . . . . . . . . . . . . [9]

Bottom of keyseat to opposite side of shaft, $K = (d - J - E)$ . . . . . . [10]

Top of key to opposite side of shaft, $L = (F + E + K)$. . . . . . . . [11]

Bottom of keyway to opposite side of bore, $M = (d - J + G)$ . . . . . [12]

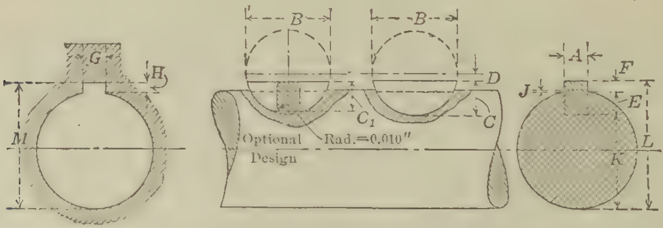

FIG. 5. Standard Woodruff Key and Keyseat

**The Barth Key.**—The key shown in Fig. 6 was devised by Carl G. Barth to combine the advantages of the Lewis key with those of the ordinary rectangular key. The Barth key is rectangular, with one-half of both sides bevelled at 45 deg. The key does not need to fit tightly, as pressure tends to drive it into its seat. There is no tendency to turn it, and the only stress to which it is subject is compression. This key has been used in many cases as a feather to replace rectangular feather keys which have given trouble. It has found wide application as a feather key in drill sockets and drill shanks, reamers, etc., which are commonly driven with a tang. Dimensions are given in Table 7.

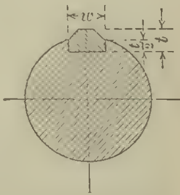

FIG. 6. Barth Key

Reducing sockets for drill presses are fitted with a Barth key dovetailed inside and a similar keyway on the outside. No. 1 Morse taper shank has a keyway for No. 1 Barth key and fits into a No. 1 reducing socket. No. 2 shank has No. 2 Morse taper and a keyway for No. 2 Barth key, etc. Dimensions of the various sizes of the dovetailed Barth key as used for sockets are shown in Table 8. The Barth key has been adapted to a complete line of standard taper sockets, shanks, driving keys, holdback keys, drifts, adapters, and reducers at the Watertown

Arsenal. The standards, which cover both Brown & Sharpe and Morse tapers are given in *Am. Mach.*, Dec. 24, 1914.

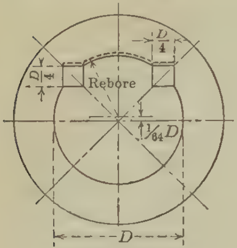

FIG. 7. Kennedy Key

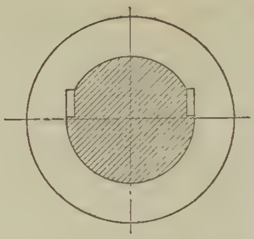

FIG. 8. Lewis Key

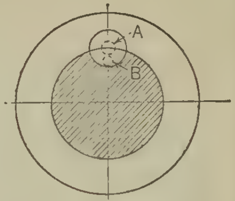

FIG. 9. Nordberg Key

**The Kennedy Key.**—The Kennedy key, largely used in rolling mill work, is shown in Fig. 7. In these keys, $w = t = {}^1/_4\,D$. They are tapered $^1/_8$ in. per foot on top, while the sides are a neat fit. The keys are so set in the shaft that diagonals through them intersect at the axis of the shaft. If in assembling, the hub is to be slid along the shaft for a considerable distance, the hub is bored for a press fit and then is rebored eccentrically about $^1/_{64}\,D$ off center. The keyways are cut in the eccentric side. General practice is to use single keys for diameters up to and including 6 in. where the torque is constant and the power transmitted always in one direction. For shafts above 6 in. diameter double keys should be used, and if the torque is intermittent and in alternate directions, double keys should be used down to shaft diameters of 4 in.

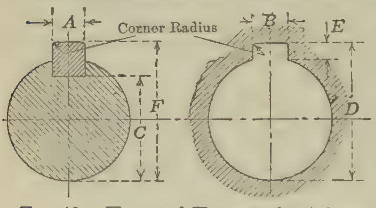

FIG. 10. Keys and Keyways for Arbors and Milling Cutters

Fig. 8 shows a key devised by Wilfred Lewis, which is similar in principle to the Kennedy key and which is used for lighter service, as machine tool work. It is subject to compression only but it has the disadvantage of being expensive and difficult to fit.

**The Nordberg Key.**—The Nordberg Mfg. Co. has adopted for the ends of shafts the round keys shown in Fig. 9. The advantages of this key are: No tendency toward deformation; they are a driven fit in the direction of the shear; they are always in true shear and are cheaper than the square key. In manufacturing, a hole *A* is drilled in the joint, and next a hole *B* as large as the size of the keyway will admit is drilled in the shaft in order to avoid the tendency of the drill used for drilling the keyway to size to crowd into

the soft cast iron. Dimensions are given in Table 9. In the table, the reamer diameters given are of the small end. The taper is $^1/_{16}$ in. per ft., measured on the diameter.

**Keys and Keyways for Arbors and Milling Cutters.**—Table 10 gives dimensions and tolerances of keys and keyways for milling cutters and arbors, as developed by the American Standards Association.

## 2. LIGHT KEYS

Where only small amounts of power are to be transmitted and it is impracticable or inadvisable to use a sunk key, a key driving on a flat, or a saddle key may be used. These two types of key drive mainly by friction.

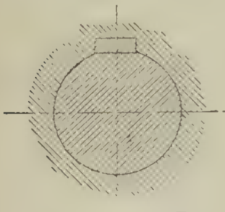

FIG. 11. Key on Flat

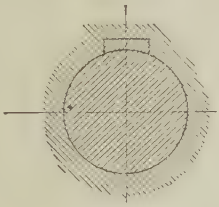

FIG. 12. Saddle Key

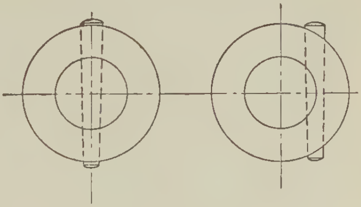

FIG. 13. Pin Keys

**KEY ON FLAT.**—If a small flat be milled or filed on the shaft, a flat key with a slight taper may be driven into a keyway in the hub opposite the flat on the shaft. See Fig. 11. This type of key is suitable for transmission of light powers, and has the advantage of ease of assembling. Such a key should not be subjected to sudden changes in torque, as it then may slip on the shaft and seriously damage it.

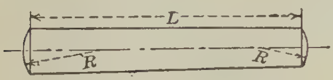

FIG. 14. Taper Pin

**SADDLE KEY.**—The saddle key, Fig. 12, depends entirely on friction to prevent motion of the hub relative to the shaft. The key is driven into a keyway in the hub, and the face of the key bearing on the shaft is made with a radius somewhat smaller than the radius of the shaft. The key should have a slight taper.

**PIN KEYS** are adapted to transmit power with light loads. Fig. 13 shows two methods of using taper pins as keys. Table 11 gives the dimensions of standard taper pins.

**FEATHER KEYS** are used when the hub must slide axially along the shaft, but at the same time rotate with it. The feather key is a sunk key. It either may be dove-

tailed into the shaft, or fastened in place by screws. Fig. 15 shows various forms. If the key is required to slide with the hub, the construction shown in Fig. 15 *c* may be used. Instead of feather keys, spline shafts now are largely used.

## 3. SPLINES AND SQUARE SHAFTS

Instead of keys, spline shafts, or squared shafts may be used for the transmission of power from a shaft to a hub or *vice versa*. These applications are found in geared transmissions, machine tool drives, and in automotive work.

**MULTIPLE SPLINES** are, in effect, a series of parallel keys formed integral with the shaft, mating with corresponding grooves cut in the hub or fitting. They are particularly useful where the hub must slide axially on the shaft either under load or free from load. Spline fittings with four, six, ten and sixteen splines have been standardized by the S.A.E. Dimensions of these standardized fittings are given in Table 12 and Fig. 16. The relations between the internal diameter of the fitting and depth of spline are given in Table 13.

**Torque Capacity of Spline Fittings** may be determined by the formula

$$T = 1000\,N\,r\,h \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \qquad [13]$$

where $N$ = number of splines; $r$ = mean radial distance from center of hole to center of spline; $h$ = depth of spline; all in inches. This formula is based on a pressure of 1000 lb. per sq. in. on the sides of the spline.

**SQUARE SHAFTS.**—Table 14 and Fig. 17 give the proportions of square shafts and fittings as standardized by the S.A.E. For transmissions in which the hub or fittings must slide on the shaft, it is recommended that the ratio of the width across the flat to the width across the corners of the shaft, that is $A/B$, Fig. 17, be made equal to 0.73. If the hub or fitting is not to slide on the shaft, it is recommended that $A/B = 0.80$. It is recommended that holes be made to a standard size both for sliding and permanent fits, and that the size of the shaft be varied in accordance with the service required. The proportions given in Table 14 assume that the hub or fitting is not hardened and that the shafts may be either hardened or soft.

[1] Tolerance allowed of −0.0010 in.

[2] Tolerance allowed of −0.0050 in.

[3] Tolerance allowed of −0.0010 in., for shafts 3/4 to 1 3/4 in. inclusive; −0.0015 in. for shafts 2 to 2 3/4 in., inclusive; −0.0020 in. for shafts 3 to 4 in., inclusive.

[4] Tolerance allowed of −0.0080 in. for shafts 1/4 to 5/8 in. inclusive; −0.0150 in. for shafts 3/4 to 4 in., inclusive.

[5] Tolerance allowed of −0.005 in.

[6] Tolerance allowed of −0.008 in. for shafts 1/4 to 7/8 in. inclusive; of −0.015 in. for shafts 1 in. to 4 in. inclusive.

## COTTERED JOINTS

A cotter is a form of key used to join parts that are subjected to a tension or compression, tending to separate them. The taper of cotters should not exceed $1/2$ in. per ft. of length unless a locking device is used. Various forms of cotters are given in Figs. 1 to 7,

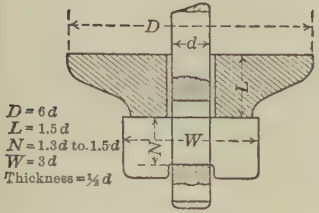

FIG. 1

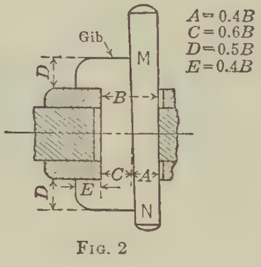

FIG. 2

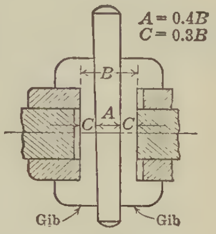

FIG. 3

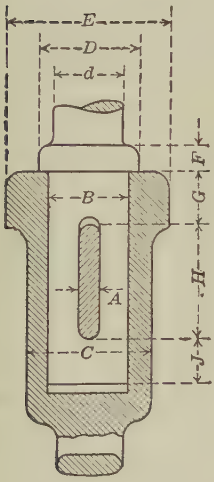

FIG. 4

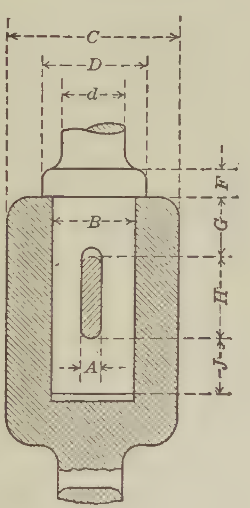

FIG. 5

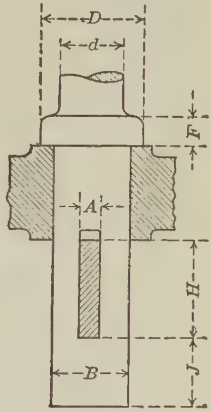

FIG. 6

and in Table 1 which shows the proportions of the joint. The function of the gib, in the gib and cotter joint, Figs. 2 and 3, is to prevent spreading of the strap. When a gib is used, the sides of the hole are made parallel, the taper being given to the gib. Where two cotters are used, as in Fig. 3, the taper is divided equally between them. The tapered joint, Fig. 7, usually is of permanent character. The cotter is removed only when the members which it holds are to be repaired or replaced. It is largely used for joining pistons and piston-rods.

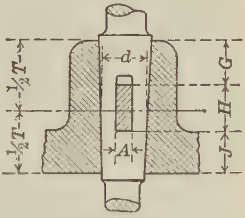

FIG. 7

**Table 1.—Dimensions of Cottered Joints.** (See Figs. 4–7)

| | Rod | Cotter | Dimensions | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | *A* | *B* | *C* | *D* | *E* | *F* | *G* | *H* | *J* |

| Fig. 5 | W. I. | Steel | 0.3*d* | 1.21*d* | 2.42*d* | 1.5*d* | ...... | 0.42*d* | 0.8*d* | 1.25*d* | 0.8*d* |
| Fig. 6 | Steel<br>W. I. | Steel<br>W. I. | 0.3*d* | 1.21*d* | ...... | 1.5*d* | ...... | 0.5*d* | ...... | 1.6*d* | 1.0*d* |
| Fig. 7 | Steel | Steel | 0.25*d* | ...... | ...... | ...... | ...... | ...... | 0.9*d* | 0.9*d* | 0.9*d* |

One form of grip taken from Machine Design Construction by Spooner is shown in Fig. 8. The joint may fail in any one of ten ways as follows:

**Notation.**—$f_t$ = ultimate strength of rod ends in tension; $f_s$ = ultimate strength of cotter in shear; $f_b$ = ultimate strength of bearing surfaces = say, $2f_t$; $f'_s$ = ultimate strength of wrought iron to resist shear in direction parallel with fibers; $F$ = axial force causing rupture of the joint; all in lb. per sq. in. The significance of the other quantities in the equations is shown in Fig. 8, all dimensions being taken in inches.

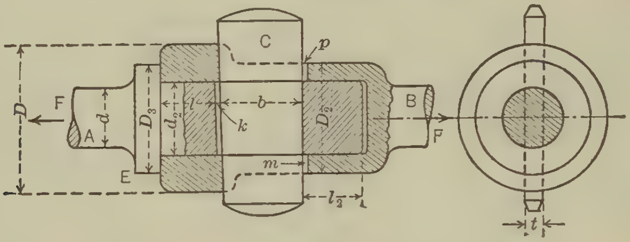

FIG. 8

1. The rods may fail in tension at A or B, in which case the external load

$$F = 1/4\pi d^2 f_t.$$

2. By the rod end tearing across the cotter hole; $F = (1/4\pi d_2^2 - d_2 t)f_t$. Equate cases [1] and [2] and let $t = 1/4\, d_2$; then

$$d_2 = 1.21\, d,\ d = 0.82\, d_2 \text{ and } t = 0.3\, d.$$

For joints with all parts either wrought iron or steel, the breadth of the cotter usually is about 1.6 $d$.

3. By the socket tearing across the cotter hole; then

$$F = \{1/4\pi(D_2^2 - d_2^2) - D_2 - d_2)t\}f_t,$$

whence by equating case [1], $D_2 = 1.63\, d$, or allowing for clearance, say, $D_2 = 1.75\, d$.

4. By double shearing of the cotter;

$$F = 2btf_s, \text{ and } b = 1.31\, df_t/f_s,$$

or 1.06 $d_2 f_t/f_s$, where $b$ = mean breadth of the cotter.

5. By crushing the cotter bearing surface in the rod end; $F = d_2 t f_b$.

6. By crushing the cotter bearing surface in socket; $F = t(D - d_2)f_b$ and $D = 2.42\, d$.

7. By shearing socket end; $F = 2\{l(D - d_2)f'_s\}$.

8. By shearing rod end; $F = 2\, l_2 d_2 f'_s$. $l = l_2 = 0.648\, d$; make $l$ from 0.75 $d$ to 1.0 $d$.

9. By crushing the collar E; $F = 1/4\pi(D_3^2 - d_2^2)f_b$ and $D_3 = 1.3915\, d$, say 1.4 $d$.

10. By shearing the collar E off the rod end; $F = d_2 \pi t_2 f'_s$ and $t_2 = 0.413\, d$, say $t_2 = 0.42\, d$.

## PINS

**STRENGTH OF KNUCKLE JOINT PIN.** (Spooner, Machine Design.)—The proportions of a forked pin joint, or knuckle joint are shown in Fig. 1. If there is no bending action, the pin will fail in double shear. If $d$ = diameter of rod, $d_1$ = diameter of the pin, $f_t$ = tensile strength of rod, lb. per sq. in., $f_s$ = shearing strength of pin, lb. per sq. in., = say, 0.8 $f_t$, then

$$1/4\pi d^2 f_t = 2(1/4\pi d_1^2 f_s), \text{ or } d_1 = 0.79\, d.$$

Unwin shows that where bending occurs and the joint is subjected to stresses reversing in sign, a skin stress of 5400 lb. per sq. in., due to bending will not be exceeded if the diameter of the pin = $0.0224\sqrt{P}$, where $P$ = axial force in the rod.

**BRIDGE PINS.**—Pins of various forms are used to connect rods or bars in groups, as in the lower chords of trusses. The pin must resist shearing, bending and bearing stresses, the latter two usually governing. Bar sizes should be so selected that the bearing area on the pin will be sufficient to avoid setting up excessive loads tending to crush either the pin or the bar. Also, bars must be so spaced that excessive bending stress is not set up in the pin. Let $M$ = moment of forces at any section of the pin; $f$ = unit stress in bending, lb. per sq. in.; $A$ = area of pin cross-section, sq. in.; $d$ = diameter of pin, in. Then

$$M = \pi f d^3/32 = f A d/8.$$

Fig. 2 shows plain pins and pins with heads, the pin being fastened with cotters. Dimensions are given in Table 1. Fig. 3 shows pins with recessed nuts. See Table 2 for dimensions. Bending moments and bearing stresses on pins are given in Table 3.

* Additional lengths, 5/16 and 7/16 in. † Increments above 1 3/4 in. are 1/4 in.
‡ First increment is 1/8 in. from 1 5/8 to 1 3/4 in.

# TAPERS

Up to 1937 there was no single standard taper in the United States for spindles and drill shanks. The more important tapers in common use were: the Sellers taper used for lathe, drilling and boring machine spindles; the Morse taper, used for drilling machine spindles and drill shanks; the Brown & Sharpe taper, used for milling machine spindles; the Reed taper, used for lathe spindles; the Jarno taper used for lathe and drilling machine spindles; the Cleveland Twist Drill Co. taper and the Standard Tool Co. taper, used for drill shanks. Dimensions of these various tapers are given in Tables 4 to 10.

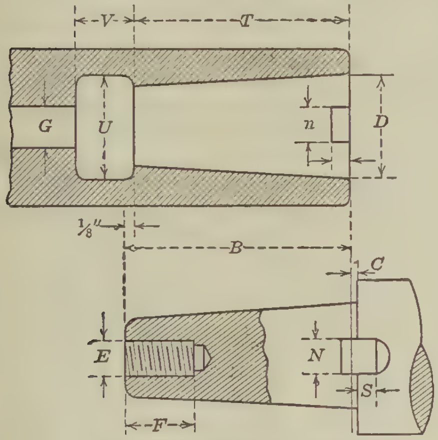

FIG. 1. Taper with Draw-bolt. See Table 1

**AMERICAN STANDARD TAPER.**—In 1937, the American Standards Association published standards for self-holding tapers which comprise 19 sizes. The three smaller sizes were taken from the Brown & Sharpe series, having a nominal taper of 1/2 in. per foot; the next six sizes were taken from the Morse series having a nominal taper of 5/8 in. per

† Corners at entrance side of keyways to be chamfered at 45 deg. as follows: No. 200 to No. 300, inclusive, 3/16 in. deep; No. 400 to No. 600, inclusive, 3/32 in. deep. No. 800 to No. 1200, inclusive, 1/8 in. deep.

foot; the ten largest sizes were based on a taper of $^3/_4$ in. per foot. The 13 smaller sizes are driven by a tongue or tang, except that the four largest sizes of this group may be driven by a key. The 13 smallest sizes are retained entirely by friction, or, in the case of the eight largest of this group, they may be retained by a holdback key. The ten largest sizes, except as noted above, are driven by a key, and may be retained in place either by a holdback key or a draw-bolt. Dimensions are given in Tables 1 to 3 and Figs. 1 to 4.

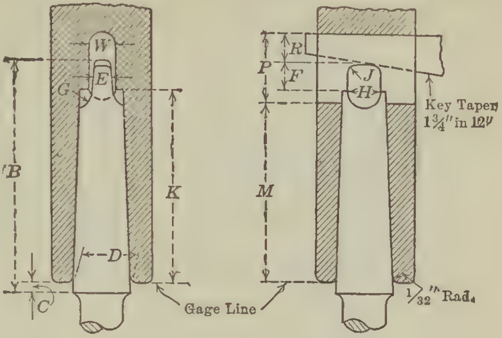

FIG. 2. Taper with Tongue Drive, Shank Retained by Friction. See Table 2

**TOLERANCES FOR AMERICAN STANDARD TAPERS.**—Diameter of Shank and Hole at Gage Line, dimension *D*: +0.002, −0.000.

**THICKNESS OF TONGUE,** dimension *E*, Table 2: From $^1/_8$ in. to $^1/_4$ in. inclusive, +0.000, −0.004 in.; from $^5/_{16}$ in. to $^{15}/_{32}$ in. inclusive, +0.000, −0.006 in.; from $^9/_{16}$ in. to 1 in. inclusive, +0.000, −0.008 in.

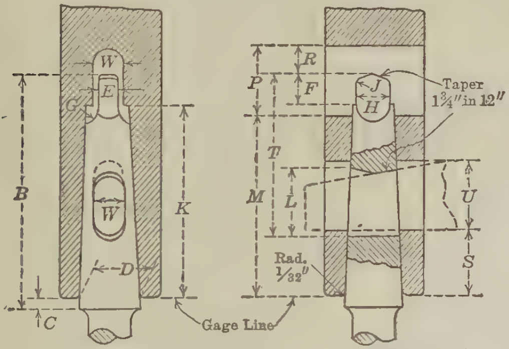

FIG. 3. Taper with Tongue Drive, Shank Retained by Key. See Table 2

**Concentricity of Tongue** with center line of taper, dimension *E*, Table 2: Tapers No. .239 to No. 4 inclusive, 0.0035 in.; tapers No. 4 $^1/_2$ to No. 350 inclusive, 0.007 in.

**Width of Keyway, Friction-retained and Key-retained Tapers,** dimension *W*, Table 2: Tapers No. .239 to No. 2 inclusive, +0.004, −0.000 in.; No. 3 and No. 4, +0.006, −0.000 in.; No. 4 $^1/_2$ to No. 350 inclusive, +0.008, −0.000; key drive tapers (Table 3) all sizes, +0.008, −0.000.

**Concentricity of Keyway,** dimension *W*, with center line of taper: Friction-retained and key-retained tapers (Table 2), tapers No. .239 to No. 4 inclusive, 0.0035 in.; tapers No. 4 $^1/_2$ to No. 350 inclusive, 0.007 in.; key-driven tapers (Table 3), all sizes, 0.007 in.

**Drive Keyway,** width, dimension *N*, Table 3: In spindle, +0.000, −0.001 in.; in shank, +0.010, −0.013 in.; width, dimension *N*, Table 1, +0.000, −0.001 in.; width, dimension *n*, Table 1, +0.003, −0.000 in.

**Tolerance on Fractional Dimensions,** for all types of tapers is +0.010, −0.010 in., unless otherwise specified.

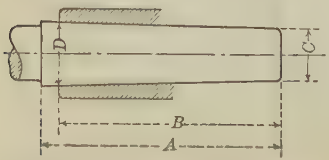

FIG. 10. Jarno Taper. See Table 10

**THE JARNO TAPER** is 0.05 in. per in. = 0.6 in. per ft. The number of the taper is its diameter in tenths of an inch at the small end, in eighths of an inch at the large end, and the length in halves of an inch. If $N$ = number of taper, $D$, $d$ = diameter at large and small ends, respectively, $L$=length, $D=N/8$, $d=N/10$, $L = N/2$. Thus, No. 3 Jarno taper is 1 1/2 in. long, 0.3 in. diameter at the small end and 3/8 in. diameter at the large end. See Table 10 and Fig. 10.

# FITS

The degree of tightness or looseness between two parts that are intended to act together is known as the fit of the parts. The character of the fit depends upon the use to which it is to be put. Thus the fit between members which move or rotate relative to each other, as a journal rotating in a bearing, is considerably different from the fit which is designed to prevent any relative motion of the fitted members as, for example, a tire fitted to a locomotive driving wheel center.

Manufacturers and engineering associations have adopted in the past many different standards for fits to meet their particular needs. For details of these practices, see earlier editions of this book and also *Machinery's Handbook*, 9th Edition. In 1925, the American Standards Association published standards for fits, tolerances and allowances for all classes of service. These standards are abstracted below. For fits in journal bearings, see p. 13–31.

**TERMS RELATING TO FITS.**—**Basic Size** is the exact theoretical size from which all limiting variations are measured.

**Allowance** is an intentional difference in the dimensions of mating parts, or it may represent the minimum clearance space that is intended between mating parts. It represents the tightest permissible fit, *i.e.*, the largest internal member mated with the smallest external member.

**Tolerance** is the amount of variation permitted in the size of a part. In manufacturing a large number of pieces, it is not possible to produce them to identical dimensions, and the tolerance allows variations from the basic size that will permit them to be produced, but which will not prevent their proper functioning. Variations must tend toward greater looseness than the ideal conditions of the smallest hole, or external member, and the largest shaft, or internal member. Tolerances should be stated on the drawing by giving the basic size and the maximum and minimum permissible variations therefrom. Thus,

$$\text{Shaft, 0.874 in.}\left\{\begin{matrix}+0.000\text{ in.}\\-0.001\text{ in.}\end{matrix}\right.;\quad \text{Hole, 0.875 in.}\left\{\begin{matrix}+0.001\text{ in.}\\-0.000\text{ in.}\end{matrix}\right.$$

This indicates a manufacturing tolerance of 0.001 in. on each part. The clearance with the greatest possible looseness is 0.003 in., and with the greatest possible tightness, 0.001 in.

**Limits** are the extreme permissible dimensions of a part.

**CLASSIFICATION OF FITS.**—Fits are classified as follows:

**Class 1, Loose Fit, Large Allowance.**—This fit provides for considerable freedom and embraces certain fits where accuracy is not essential. Examples of its use are the machined fits on agricultural and mining machinery, control apparatus for marine work, machinery in the textile, rubber and canning industries, and general machinery of similar grades. It is used for strictly interchangeable assembly. Tolerances and allowances are determined by the following formulas, in which $d$ = diameter of fit, in inches:

$$\text{Allowance} = 0.0025\sqrt[3]{d^2};\quad \text{hole tolerance and shaft tolerance} = 0.0025\sqrt[3]{d}.$$

Dimensions are given in Table 1.

**Class 2, Free Fit, Liberal Allowance.**—This fit is designed as a running fit for speeds of 600 r.p.m. or over, and journal pressures of 600 lb. per sq. in. or more. Examples of its use are electric generators, engines, machine tool parts, and automotive parts. It is used for strictly interchangeable assembly. Allowances and tolerances are determined by the following formulas:

$$\text{Allowance} = 0.0014\sqrt[3]{d^2};\quad \text{hole and shaft tolerance} = 0.0013\sqrt[3]{d}.$$

Dimensions are given in Table 1.

* Minimum limit = 0.0000 in. for all sizes.

‡ Maximum limit = 0.0000 in. for all sizes.

† Plus here denotes clearance or amount of looseness.

§ Tightest fit allowance = 0.0000 for all sizes.

**Class 3, Medium Fit, Medium Allowance.**—This fit is designed for running fits under 600 r.p.m. and with journal pressures of less than 600 lb. per sq. in. It also is used for sliding fits, and the more accurate machine tool and automotive parts. It is designed for strictly interchangeable assembly. Allowances and hole tolerances are determined by the following formulas:

$$\text{Allowance} = 0.0009\sqrt[3]{d^2};\ \text{hole tolerance and shaft tolerance} = 0.0008\sqrt[3]{d}.$$

Dimensions are given in Table 2.

**Class 4, Snug Fit, Zero Allowance.**—A snug fit is the closest fit that can be assembled by hand. It necessitates work of considerable precision. It is used where no perceptible shake is permitted, and where moving parts are not intended to move freely under load. An example of its use is the assembly of the body and jaws of a drill chuck. It is designed for strictly interchangeable assembly. Allowance = 0.0000. Hole and shaft tolerances are determined by the following formulas:

$$\text{Hole tolerance} = 0.0006\sqrt[3]{d};\ \text{shaft tolerance} = 0.0004\sqrt[3]{d}.$$

Dimensions are given in Table 2.

**Class 5, Wringing Fit, Zero to Negative Allowance.**—This fit also is known as a *tunking fit*. It is practically a metal-to-metal fit. Assembly usually is selective and not interchangeable. Examples of its use are locating keys, tongues or dowels. The selected average interference of metal is 0.0000 in. Hole and shaft tolerances are determined by the following formulas:

$$\text{Hole tolerance} = 0.0006\sqrt[3]{d};\ \text{shaft tolerance} = 0.0004\sqrt[3]{d}.$$

Dimensions are given in Table 3.

**Class 6, Tight Fit, Slight Negative Allowance.**—These fits are used where parts are to be more or less permanently assembled, and light pressure is required in the assembly operation. They are used for drive fits in thin sections, or very long fits in other sections, and also for shrink fits on very light sections. Examples of the use of this fit are jig bushings, and fixed ends of studs for gears, pulleys, rocker arms, in automotive, ordnance

* Minimum limit = 0.0000 in. for all sizes.

† Minus here denotes interference of metal or negative allowance.

‡ Plus here denotes clearance or amount of looseness.

and general machine manufacturing. In this fit, the average interference of metal is the desired condition. It must be obtained by selective assembly, *i.e.*, by mating large shafts in large holes, and small shafts in small holes. In this fit, selected average interference of metal = 0.00025 $d$. Hole tolerances and shaft tolerances are given by the formula

$$\text{Tolerance} = 0.0006\sqrt[3]{d}.$$

Dimensions are given in Table 3. The stresses set up in the members, and the forces required for making these fits, are given in Table 4. The values of the greatest hole stress in Table 4 are for mean diameters only. For other sizes in the same group, the interference per inch of diameter, and hence the greatest hole stress will vary from the values given by less than 10%. If greater accuracy for intermediate steps is required, the interference per inch of diameter should be computed by the formula given above. The values given in Table 4 are true only when hub diameter equals twice the hole diameter.

**Class 7, Medium Force Fit, Negative Allowance.**—These fits are used where the parts are to be permanently assembled. Considerable pressure is required for assembly. They are the tightest fits recommended for cast iron holes or external members, since they will stress cast iron to its elastic limit. Examples of the use of this class of fit are the attachment to their axles or shafts of locomotive and car wheels, generator and motor armatures, and engine crank discs. This class of fit also is used as a shrink fit on medium sections or long fits. These fits are used for selective assembly only. Selected average interference of metal = 0.0005 $d$. The shaft and hole tolerances are determined by the formula

$$\text{Tolerance} = 0.0006\sqrt[3]{d}.$$

Dimensions are given in Table 5. Stresses set up in the parts, and the pressure required to make the fits, are given in Table 6. The values given in Table 6 for stress and force are true only when the hub diameter equals twice the hole diameter. The values of

* Interference of metal on selected fits, all sizes, = 0.00025 in.
† Greatest stress in hole on selected fits, all sizes, = 7250 lb. per sq. in.
‡ Greatest stress in hole on selected fits, all sizes, = 2608 lb. per sq. in.
§ $A$ = allowance; $d$ = mean size.

greatest hole stress are for mean diameter sizes only. For other sizes in the group, the interference per inch of diameter, and hence the greatest hole stress will vary from the values given by less than 10%. If greater accuracy for intermediate steps is required, the interference per inch of diameter should be computed by the formula given above.

**Class 8, Heavy Force and Shrink Fit, Considerable Negative Allowance.**—These fits are used for steel holes where the metal can be highly stressed without exceeding its elastic limit. They cause excessive stress in cast-iron holes. Shrink fits are used where heavy force fits are impracticable, as on locomotive wheel tires, heavy crank discs, etc. They are for selective assembly only. Selected average interference of metal = 0.001 $d$. Hole and shaft tolerances are given by the formula

$$\text{Tolerance} = 0.0006\sqrt[3]{d}.$$

Dimensions are given in Table 7. Stresses set up by, and the force required to make these fits, are given in Table 8. The values given in Table 8 for stress and force are true only

| | | | Stress = 29,000,000A/d§ | | Stress = 10,432,000A/d§ | | Force = 1298 A § | | | Force = 747.2A § | | |

Note 1.—No values are given for sizes 1/8 in. to 1 1/4 in. inclusive, because of the absence of interference of metal, due to the smallest shaft member being smaller than the largest hole member.

* Interference on selected fits, all sizes, = 0.0005 in.

† Greatest hole stress on selected fits, all sizes, = 14,500 lb. per sq. in.

‡ Greatest hole stress on selected fits, all sizes, = 5216 lb. per sq. in.

§ $A$ = allowance; $d$ = mean size.

when the hub diameter equals twice the hole diameter. The values of the greatest hole stress are for mean diameter sizes only. For other sizes in the group, the interference per inch of diameter, and hence the greatest hole stress, will vary from the values given by less than 10%. If greater accuracy for intermediate steps is required, the interference per inch of diameter should be computed by the formula given above.

STRESSES RESULTING FROM FORCE FITS.—In any force or shrink fit, the metal of the fitted member is deformed by an amount equal to the interference of metal between the external and internal members. Discussions of the stress set up by this deformation usually are based on the assumption that the materials are elastic and follow Hooke's law.

* Minus here denotes interference of metal or negative allowance.
† Plus here denotes clearance or amount of looseness.

A. Lewis Jenkins (*Am. Mach.*, March 4, 1915) shows that for the usual combination of a cast-iron hub shrunk on a steel shaft, Hooke's law does not apply to the cast-iron hub. From a study of a wide variety of force and shrink fits, he deduced the following equations: Let $p$ = the unit stress between shaft and hub; $r_2$ = common radius of fitted shaft and hub; $r_3$ = external radius of hub; $e$ = total deformation of shaft and hub in pressing $= r_s - r_h$; $r_s$, $r_h$ = respectively, external radius of shaft and internal radius of hub before pressing. Then for cast-iron hubs on steel shafts

$$p = \{102{,}900{,}000\ (e/r_2)\} \div \{7.16 + (r_3/r_2)\}.$$

For steel hubs on steel shafts

$$p = [15{,}000{,}000\ (e/r_2)\{(r_3/r_2)^2 + 1\}] \div \{(r_3/r_2)^2\}.$$

In designing force and shrink fits, the interference $e$ usually is assumed. The resulting stress then should be calculated to make sure that the elastic limit of the material is not exceeded.

### Table 8.—Stresses and Forces for Heavy Force and Shrink Fits, Class 8

A.S.A. B4a–1925

Force values are for fits 1 in. long. For longer fits, multiply tabular values by length of fit in inches

| 128 | .00102 | .00098 | .001 | 29,690 | 28,320 | 29,000 | 170.038 | 162.250 | 166.144 |
| | | | | Stress = 29,000,000 $A/d$ * | | | Force = 1298$A$ * | | |

* $A$ = allowance; $d$ = mean size.

NOTE 1. No values are given for sizes 1/8 in. to 1/2 in. inclusive because of the absence of intererence of metal, due to the smallest shaft member being smaller than the largest hole member.

**TEMPERATURES FOR SHRINKAGE FITS.**—The temperature to which the outer member in a shrinkage fit must be heated in order to assemble the parts depends upon the coefficient of linear expansion of the metal. For wrought iron and steel this is about 0.000 0065 for each degree F. and for cast-iron it is 0.000 0062. Low redness corresponds to about 900° F. and hence causes an expansion of the bore of about 0.005 in. per in. of diam.

# BEARINGS AND LUBRICATION

## CLASSIFICATION

Bearings may be classified according to Function, Form, Design, and Lubrication.

**CLASSIFICATION BY FUNCTION.**—Bearings may be defined according to function as follows:

**Radial Bearing.**—A bearing applied to a rotating shaft to hold its axis in line, and prevent movement in a radial direction.

**Thrust Bearing.**—A bearing applied to a shaft to prevent free endwise movement.

**Angular Bearing.**—A bearing to constrain a shaft against both radial and axial movement; the load is received in an angular direction and has radial and axial components.

**Guides or Ways.**—Bearings to permit and control the rectilinear movement of a sliding machine element, as a ram or crosshead, or slide. Guides usually are designed to prevent rotational movement of the sliding element.

**CLASSIFICATION BY FORM.**—Bearings may be divided into the following forms, depending on the way in which friction is produced in them:

**Sliding Surface Bearings** include all that depend on lubricating films, perfect or imperfect, of oil, grease, graphite or other material.

**Rolling Contact Bearings** include all forms of ball and roller bearings.

**Sliding Rolling Face Bearings** include those found in gear teeth, cams, and some forms of roller bearings.

**CLASSIFICATION BY DESIGN** may be made as follows:

**Self-aligning Bearings** are those in which the parts will automatically align themselves when assembled and loaded.

**Rigid Bearings.**—Bearings in which bearing surfaces are practically invariable in form and position after installation. Also known as non-aligning bearings.

**Pivoted Segment Bearings.**—Bearings in which one of the active surfaces is made up of segments so freely mounted as to permit the formation of natural wedge-shaped lubricating films.

**Elastic Bearings.**—Those in which one of the active surfaces is elastic or elastically supported so as to flex with respect to the other for the purpose of alignment and film formation.

**CLASSIFICATION BY LUBRICATION.—Bath Lubricated Bearings.**—Bearings in which active surfaces always are submerged in a well of lubricant.

**Automatically Lubricated or Self-oiling Bearings.**—Bearings in which the rotation of the shaft or movement of parts causes lubricant to be applied continuously to the bearing surfaces.

**Independent Pressure-lubricated Bearings.**—Bearings lubricated from a pressure source, independent of the bearing mountings, which may be operated before the machine is started, or may be geared into the machine, operating only when the machine runs. The system is then known as *Automatic Pressure Lubrication.*

**Periodically-lubricated Bearings** include all those using any form of intermittent application, by whatever means the lubricant is applied.

**FACTORS IN BEARING DESIGN AND OPERATION.**—The several factors listed below are important to the designer and user of bearings, from the standpoint of permissible loads, lubrication, etc.

**Surface Speed** rarely is a limitation with perfectly lubricated bearings. See Cooling of Bearings, p. 13–52.

**Straight-line Motion** of sliding bearing surfaces may be continuous in one direction, as wire in a drawing die. It may be intermittent in one direction as in the ram of a ratchet jack. It may be reciprocating motion, as in crossheads or machine guides.

**Circular Sliding Motion,** as in journal, thrust, and angular bearings may be continuous in one direction, or it may be reversible, *i.e.*, rotation in opposite directions for equal or unequal periods of time. It may be oscillating, as in a shaft carrying a rocking lever, or intermittent as in bearings for a ratchet wheel shaft. The angle of rotation is important in the last two classes.

**Approach and Recession** of bearing faces frequently is superimposed on sliding motion, as in rocking levers, wrist pins, and reversing shafts. It is caused by change in magnitude of bearing load, by reversal, shock or other cycle of load variation.

**Rotating Radial Load** is found more often in vertical than in horizontal shafts. It is an unusual condition, generally due to lack of balance, accidental or otherwise, but which may result as in rock crushers from the process of manufacture carried on in the machine.

# OIL FILM BEARINGS WITH PERFECT LUBRICATION

**By H. A. S. Howarth**

## 1. JOURNAL BEARINGS

**CLASSIFICATION.**—Bearings may be integral with the machine frame or separate and bolted thereto. The *bearing surface* may be *a*, integral with the machine frame; *b*, integral with an element of it called the bearing; or *c*, formed on a replaceable shell. The bearing surface usually is formed of softer metal than the material of the machine frame or of the bearing shell. See Bearing Metals, p. 4–62. If the bearing metal is cast into spaces in the machine frame, it would be classed as an integral bearing, as it is not readily replaceable. Hence, bearings may be classified broadly as integral or renewable bearings.

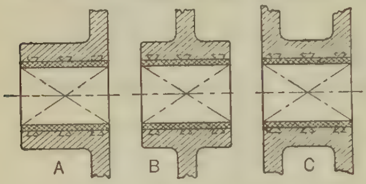

FIG. 1. Integral Bearings

**Integral Bearings.**—In the design of bearings, shaft deflection should be considered so that the deflection of the bearing, if appreciable, will tend to match that of the shaft. In Fig. 1, designs A and B may compensate for shaft bending. Design C conveys the idea of rigidity.

Integral bearings may be solid or split. The simplest joint is a plane kept in alignment by tapered or cylindrical dowels or fitted bolts. See Fig. 2. Fig. 3 shows a form of integral bearing commonly used in heavy machinery and in the bases of engines whose bearings invariably are capped. The vertical faces *aa* should fit closely and be of adequate area. Shims between the cap and frame take up clearance that otherwise might develop a bearing knock. Better forms of this type of bearing are those with a renewable shell, shown in Figs. 6 and 7.

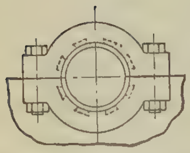

FIG. 2. Simple Split Bearing

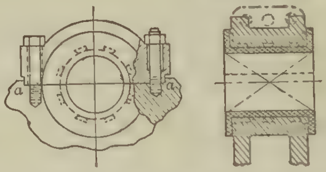

FIG. 3. Integral Bearing for Heavy Machinery

**Renewable Bearings.**—In general, renewable bearings have shells that either are *fixed* or *self-aligning*. The simplest form of renewable bearings is a plain cylindrical shell, lined or unlined, as in Fig. 4, which is a plain shell held by a dog-pointed set screw. It cannot stand much endwise bumping. Other forms are: Single-flanged shell, Figs. 5 and 11A, the former being used either split or solid; double flanged shells, Figs. 6A and 11B, which may be solid or split. Figs. 6B and 11C are forms of shell that have advantages in oil application not possessed by the others. The foregoing fixed shells in some instances may be used as renewable linings for self-aligning shells.

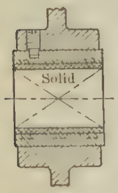

FIG. 4. Plain Renewable Shell

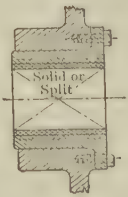

FIG. 5. Single-flanged Shell

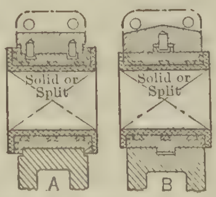

FIG. 6. Shells with Babbitt Faced Ends

The shells in Fig. 7B and C may be fixed or self-aligning, depending on the proportions and the amount of end play at the faced portions of the frame or mounting. They may be solid, or split and bolted. Because of their limited contact with the frame, the shells should be made strong and fairly hard. A soft metal lining is used in the larger sizes and in all sizes where the shell is of soft steel.

Self-aligning shells are used where ready alignment with the shaft journals is required at installation or under shaft deflection in service, or to compensate inaccuracies produced by assembly of parts, by warping, by machining, and by frame deflections. The original alignment may have to be maintained or to change with operating conditions, and shells should be designed for correction of initial and subsequent misalignment. The ball-seated shell is widely used in shaft hangers, pillow blocks and pedestals. The diameter of the spherical seats relative to the shaft is governed by the load to be carried. In general, the smaller the sphere the easier will it align the shell. Also the wider the shell, the easier it will align itself on a given spherical fit. Consequently, narrow, heavily-loaded bearing shells will not be sensitively self-aligning with the spherical proportions of Fig. 8A. Those of Fig. 8B are better. Fig. 8C shows a shell with adjustable sphere diameter used for heavy machinery. Careful setting of spherical clearances will allow for expansion in operation. The spherical angle should be as large as practicable.

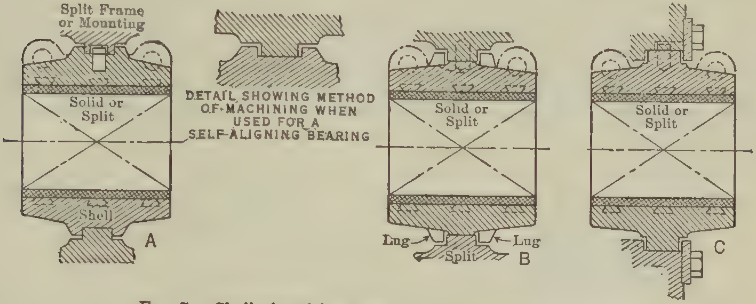

Fig. 7. Shells for either Fixed or Self-aligning Bearings.

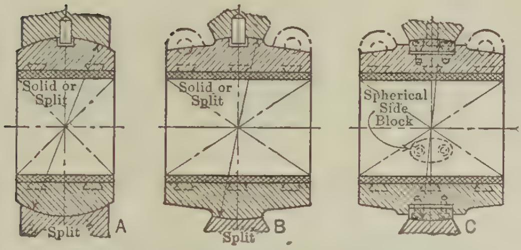

Fig. 8. Spherical-seated Self-aligning Shells

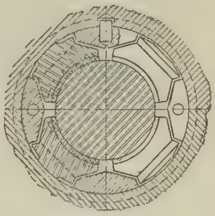

Fig. 9. Pivoted-shoe Shell, Self-aligning

The pivoted-shoe shell, Fig. 9, may be used in the space provided for an ordinary shell, like Fig. 7A, if the latter has ample cavity. Under ordinary conditions, the pivoted-shoe bearing would not be used, because its capacity generally is less than the plain journal bearing shell of similar dimensions, but under special conditions it is useful, as in very narrow self-aligning bearings. For heavy loads, hardened pivot contacts should be used in shoes and mountings.

A bearing shell with a relatively thin web, Fig. 10, can flex enough to satisfy minor shaft deflections or small errors in alignment. This form has possibilities when combined with the frame of the machine as in Fig. 1B.

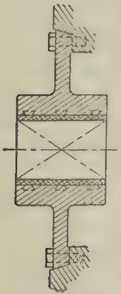

Fig. 10. Self-aligning Web-mounted Shell

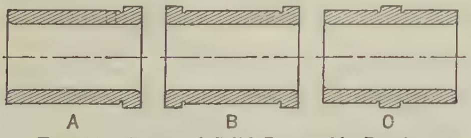

Fig. 11. Types of Solid Renewable Bearing Shells

**STANDARDIZATION OF BEARING ELEMENTS.**—Journal bearings of the film type usually are standardized as to mountings only. The fixed shell forms, Fig. 11A, B and C, lend themselves to standardization and sale of elements. Although solid bronze is widely used, there is a growing tendency to line such shells with babbitt. Many foundries carry large stocks of bronze bushings in cast form.

The self-aligning shell forms, Fig. 7, are suitable for standardization because they involve only cylindrical boring and facing of the mounting to receive them. Spherical seated shells alone are unsuited for separate sale when made as in Fig. 8, but if the two mating surfaces are sold together, as illustrated in Fig. 12, standardization is possible. The spherically bored ring around the shell of Fig. 13 has the same outside proportions as standard ball bearings offered for the same shaft. Ring oiling as shown here also is possible with bearings shown in Figs. 12A and 12C. Standardized mountings for journal bearings are available in many forms. Proportions of a few of these are given on p. 13–10. Catalogs of manufacturers of power transmission and of electrical machinery should be consulted for dimensions of other forms. See p. 24–05.

Fig. 14. Types of Shaft Collars

**CONTROL OF END PLAY.**—When no appreciable thrust load is present, end play is controlled by shoulders on the shaft. For such construction, the bearing-metal lining must bear against the shoulder as in Figs. 3, 6, 11, 12A and 13. For closer control of end play and for heavy axial loads see thrust bearing construction, p. 13–33. If the shoulder on a shaft is too small to control end play, separate collars of the forms shown in Fig. 14, are used. The face that forms the bearing should be square, flat and smooth.

**OIL GROOVES IN JOURNAL BEARINGS.**—Oil should be applied to a journal bearing at the point where there is no load, or where the load is lightest if it changes its radial direction. Grooves, therefore, may be used for the following purposes: 1. The application of oil. 2. The collection of side leakage. 3. The pumping of oil across bearing surfaces.

**Application Grooves** should be cut parallel with the shaft. The length may vary from an oil hole diameter at the middle of the bearing to the full length of the bearing surface. Such grooves usually do not extend to the sides of the bearing surface. See Fig. 15. While two such grooves frequently are cut diametrically opposite in a plane perpendicular to the direction of the load, one usually is enough. The grooves should be rounded on the edges parallel to the shaft and the raised edge resulting from cutting the groove scraped down. If the bearing revolves about a fixed shaft, the groove should be in the shaft on the unloaded side with oil supplied through the shaft to the groove.

If a load exerted by a shaft turning in a fixed bearing acts successively in all radial directions with a known portion of the shaft journal subjected to little or no load, the oil grooves should be located in the shaft at that place if practicable. Oil may be supplied to the groove through the shaft or from a ring groove at one side of the bearing, registering with one end of the groove in the shaft. Fig. 16 shows grooving for use where the direction of the radial load is unknown. This arrangement presents a fair bearing surface to the journal whenever the region of closest approach of the bearing surfaces passes over an oil groove. With pressure oiling, the circumferential groove may be omitted, thereby increasing the carrying capacity of the bearing.

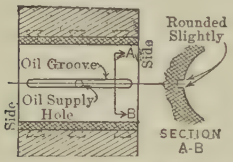

Fig. 15. Application Oil Groove

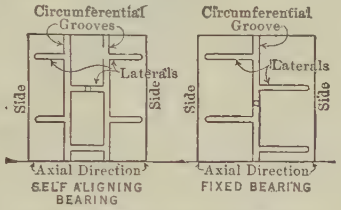

Fig. 16. Grooving where Direction of Radial Load is Unknown

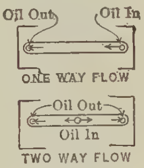

Fig. 17. Oil Grooves with Outlets

High-speed journals are cooled by continuously changing the oil. It then is necessary to provide oil outlets at the ends of the application grooves, as in Fig. 17. The grooves must be large enough to pass the desired quantity of oil with the pressure available. In Fig. 16 outlets would be provided at the ends of the laterals. The cross-section of the application groove may be, in general, similar to that shown in Fig. 15. If the grooves are used to limit the areas of the bearing surface, they sometimes are enlarged as shown in Fig. 18.

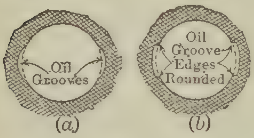

Fig. 18. Methods of Enlarging Oil Grooves

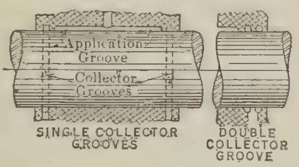

Fig. 19. Collector Grooves

**Collector Grooves** are circumferential grooves at the sides of automatically- or pressure-oiled bearings. They collect side leakage and return it to the oil well to prevent its being wasted by flow along the shaft. Such grooves usually are single, but frequently double. They should have an adequate discharge hole at the bottom. They should be continuously circumferential without a break. Oil application grooves should not enter the collector grooves. See Fig. 19.

**Pumping Grooves** are used both to pump and apply oil. The most common type is the helical groove used with a vertical shaft to lift oil from the well to the upper end of a bearing that may be higher than the surface of oil in the well. The most effective pumping groove is circumferential, if it stops short of extending all the way around the shaft, and is cut in the stationary bearing surface. The inlet end must open to the oil in the well in a manner that will readily receive oil. The other end must be dammed in the circumferential direction. From this point, suitable passages lead oil to any location within the limits of the available pressure. It simply may be led along the shaft through application grooves. Pumping grooves should be completely submerged in oil to avoid aeration of the oil bath. Aeration is, at best, hard to control in high-speed bearings.

The cross-section of a pumping groove should be shallow radially. The shallower the depth the greater will be the pressure developed, but the less the discharge. The wider the axial width the greater will be the rate of discharge. For calculations involved in design, see Viscous Flow, page 13–44. Ordinarily a simple groove of cross-section shown in Fig. 15, but shallower, will be satisfactory.

Many self-contained systems have been devised to lubricate the journal and thrust bearings of a machine continuously, which cause oil to flow to all surfaces needing it, and then return it to the well. Bearings so lubricated are durable and require a minimum of care. See Figs. 20 and 61.

**DIRT EXCLUSION AND OIL RETENTION.**—Dirt exclusion and oil retention involve the shaft, the bearings, and the mountings. Dirt must be excluded from the mountings, as it thickens the oil and closes passages and grooves. Grit in the oil scores shaft and bearing, and may cause overheating and seizing.

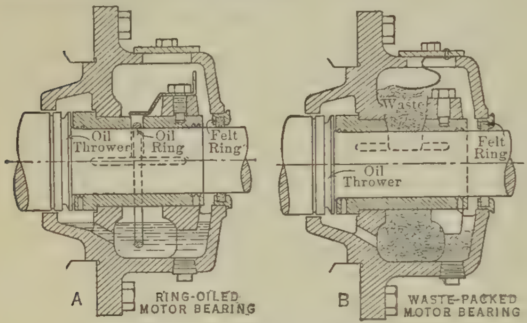

Fig. 20. Motor Bearings

In motor bearings, as Fig. 20, the problem is relatively simple because of high speed of the shaft. During operation, oil flows away in the collector grooves at the right and left and on the face of the bushing back into the well. When rotation ceases, oil drips off the shaft close to the bushing. The oil thrower at the left prevents oil leaking through the housing and the felt ring at the right excludes dirt. The oil ring, or the waste packing, lifts more oil than is needed, most of which runs back between the webs that hold the bushing. Side leakage from the bearing film is mostly taken by the collector groove and a little flows away at the faces of the bushing.

**CLOSURES.**—Conditions to be guarded against by closures include: 1. Creeping of oil along the shaft away from the bearing surfaces. 2. Rising of oil level within bearing mounting, with a tendency to overflow where the shaft passes out. 3. Collection of foam on the surface of oil within the mounting. 4. Continuing presence of contamination outside mounting at shaft opening, which may be dust or other impalpable material, abrasive particles, water or other liquids, or injurious vapors or gases. The type of closure will depend on the speed of the shaft the quantity of contamination, and the tendency of oil to flow from the mounting. High-speed shafts are easier to protect than those operating at low speeds.

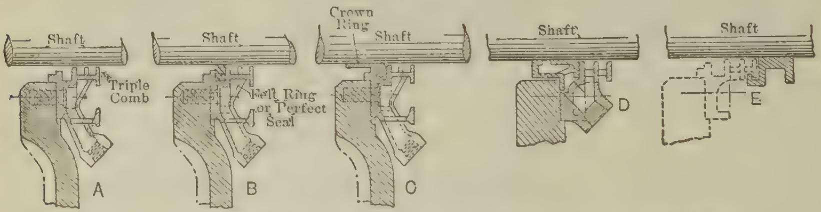

Fig. 21. Closures, Plain, with Felt, and with Crown Ring, for Large Shafts

Various closure designs are shown in Figs. 21 and 22. Those in Fig. 21 are the simplest, and require a minimum of pattern expense for a given shaft diameter. Fig. 21A is a simple comb, made in halves, bolted together, and held against the bearing mounting by cap screws. A small oil pocket is formed at the bottom between the second and third rings of the comb. Both of the outer spaces are drilled at the bottom. This comb closes the space between the mounting bore and the shaft, when the mounting is not bored with a close clearance. The comb is of brass or bronze, with a clearance around the shaft a little greater than the running clearance in the bearing. The shaft would not be harmed by contact with the soft comb. The simple comb will not prevent oil from creeping outward, but will prevent outer contaminations from working inward.

In Fig. 21B, a felt ring is added to the comb, and is fairly effective against dust entering the mounting. It tends to prevent oil leaking outward but is not reliable for this purpose. The felt ring is held in place by several pins, not shown, that pass through it axially, two being close to the joint in each half. The thickness of the felt, from which the ring strip is cut, is the axial width of the ring, so that the felt does not pucker when bent against the shaft.

If oil tends to creep outward along the shaft, the patented crown ring closure, Figs. 21C and 22, is very effective in retaining the oil. This ring is made to fit the recess in the simple comb, Fig. 21A. If a quantity of oil flows along the shaft, there may be some small leakage past the ring, which can be collected and carried to the oil reservoir of the bearing through the drain at the bottom. However, the crown ring runs usually without leakage.

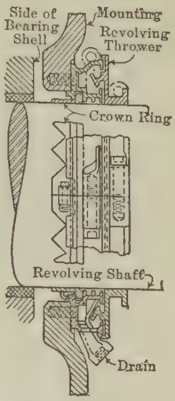

FIG. 22. Dredge Pump Bearing Arranged to Retain Oil and Exclude Water.

If a continuous head of oil is to be held or if the amount to be restrained is so great as to practically constitute a head of oil on the closure, the crown ring must be supplemented by an additional seal ring, as shown in Fig. 21D. The comb ring that retains this double seal crown ring requires longer cap screws to hold it, and it must be centered on the outside of the flange. Some oil always will leak past the larger outer flange of the floating double seal crown ring, and past its sealing band that encircles the shaft at the left of the crown. This oil must be led away from the comb to a sump, which may be in the bearing housing, and whose level is below the lower side of the shaft.

The water thrower, Fig. 21E, made in halves, can be used with any of the foregoing closures, as indicated by the dotted lines adjacent to the ring section. It protects the closure against the entrance of water or other external contaminations.

The closure, Fig. 22, is used for journal bearings having openings adjacent to sources of serious water contamination, as leakage from the packing of a pump shaft. The comb is double flanged, enabling the closure to carry away a large volume of water, with a minimum of leakage into the space between the outer flange and the comb. Any water that may pass is drained at the bottom of the space. The double-flange closure can be made in the four forms corresponding, respectively, in general function with the designs of Fig. 21. In the closures shown in Figs. 21A and B, the oil take-off shown may be omitted if the amount of leakage is small.

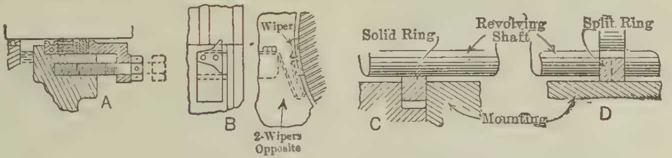

FIG. 23. Seal Rings for Retaining Oil

**PACKING AND SEAL RINGS.**—The common closure with packing, Fig. 23A, usually has two rings of packing. If a considerable head of oil is to be held in a bearing, three or four rings of packing may be used, to avoid setting up the packing very tight. Woven square packing constitutes a nearly rigid form of closure, with insufficient elasticity to permit the shaft to change position naturally within its bearing without permitting leakage past the packing. Such packing tends to dry out and to become inelastic. If not occasionally renewed or set up it will develop an opening that will permit leakage. When packing is set up against a revolving shaft, best practice is to tighten sufficiently to cause the packing to fill the space between housing and shaft, and to then relax the screws and reset them very lightly against the gland ring. This practice, if there is some oil on the shaft, or lubrication in the packing itself, will tend less to cause wear of the shaft and heat it less. Packing set up injudiciously tight, will generate more heat than the bearing itself. Special types of packing are available with the woven portion wrapped in babbitt foil, or with thin strips of babbitt on the inner surface that will press against the shaft. These run cooler than ordinary packing.

**Wipers** sometimes are used to prevent flow of oil along a shaft. Fig. 23B shows one form of wiper. Two of these, opposite, may be used. A single spring wiper may be applied to the lower side of the shaft and fastened to the closure comb. The crown ring, Fig. 22, amounts to a consecutive series of wipers mounted on the edge of a continuous band of metal and set in a groove so that it can float as the shaft moves in its clearance.

**Seal Rings.**—The seal ring has largely displaced packed stuffing boxes. See Fig. 23. In Fig. 23C, running clearance is needed between ring and shaft and sliding clearance between ring and groove. The ring may or may not be keyed against rotation. If made with fixed circumference, provision must be made for expansion due to running temperature. The split ring, Fig. 22D, may be in the form of a piston ring, or in halves butted or held by screws or a spring ring.

**ADJUSTABILITY OF BEARINGS** frequently is desirable in order to align the shaft. Jack screws, or wedges and shims are used. Compensating for wear in the bearing itself is difficult and unsatisfactory. Perfect lubrication to reduce wear to a minimum, and simple renewable bearing parts are a much better solution.

**STANDARDIZED MOUNTINGS.**—The standard tendency in bearing design is to reduce the axial width of the journal. Table 1 gives dimensions of three types of mountings, Figs. 25 to 27, in which elements of a journal bearing, Fig. 24, are incorporated. The effective width of the bearing shell is based on a standard of $1.2D$, where $D$ = journal diameter. Tabulated dimensions will deviate from this standard because each nominal size of mounting covers two standard shaft diameters. The mounting dimensions given in Table 1 are suitable for standard-duty bearing shells of the pressure type and ring oiling type. The capacity of these bearings, with a maximum load of $400A^2$ lb. is given in Table 2. $A$ here is the diameter of the journal in inches.

FIG. 28. Heavy Duty Journal Bearing with Closures and Disc Oiling

**HEAVY DUTY JOURNAL BEARINGS** are bearings designed to carry loads up to about 1200 lb. per sq. in. on an area equal to the square of the journal diameter in inches. The design and minimum proportions of such a bearing of the low pedestal type are indicated in Fig. 28. The shell stiffness should match that of the shaft to compensate for deflection under load. The journal may present its load to the bearing shell either with convex or concave flexure. For extra heavy duty service, pressures range from 1000 to 3000 lb. per sq. in. See also Roll Neck Bearings, p. 13–48.

**JOURNAL BEARING CAPACITIES.**—The factors governing carrying capacity of journal bearings are more fully discussed on pp. 13–15 to 13–30.

Table 2 will be found useful for a wide range of journal bearing applications of the standard-duty, self-aligning type (see Figs. 25, 26, 27), whose loads usually range from 50 to 400 lb. per sq. in. on an area equal to the square of the journal diameter in inches. The

| 0.8 | 0.63 |
| 1 | 1.00 |
| 1.2 | 1.42 |
| 1.5 | 2.07 |

* With suitable lubricant.

loads are based on a mean viscosity of oil in the loaded side of the film of $3.4 \times 10^{-6}$ Reyn (0.235 poise), or 125 Saybolt seconds for an oil of average base. The bearings will carry heavier loads than the standard ratings. See Column 2 for load limit for mechanical strength of the mounting, with load acting toward the base. For loads above rated load, up to the maximum load values, mean film viscosity should be increased above $3.4 \times 10^{-6}$ Reyn in proportion to the increase of load for the given speed. The relation between supply temperature of oil and mean film temperature depends on the circulation rate and unit loading of the bearing. If the bearing is lubricated by a stream of oil circulated at a rate of 0.6 gal. per Hp. of friction loss in the bearing, the oil supply temperature should be approximately $(10 + W/20)$ deg. F. above the mean temperature desired in the loaded area of the bearing film, $W$ being the unit load, lb. per sq. in., on the bearing.

**VERTICAL JOURNAL BEARINGS.**—These are known also as **Guide Bearings, and Steady Bearings.** Except for the difficulty of providing automatic self-alignment and automatic self-lubrication the problem is the same as for horizontal journal bearings. In Fig. 29, the weight of the shell causes it to lie against the top of its support. If alignment is incorrect, and the pressure of the shaft is applied to the top, the shell will tip freely into proper alignment. If, however, the shaft presses first at the bottom, the shell is apt to cramp. Solutions of this difficulty are (*a*) the supporting of the bearing shell a little above the shoulder by an elastic suspension, (*b*) the use of a spherical seat, (*c*) the use of pivoted shoes (Figs. 9 and 90). Self-aligning vertical bearings seldom are needed because vertical shafts are not deflected by the weights carried by them, as are shafts in horizontal bearings. In vertical shafts the weights produce axial loads, which are carried by thrust bearings. Because radial loads are light, and for simplicity, vertical bearings usually are of the fixed type. Axial width (height) should be as small as practicable.

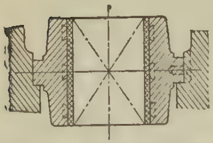

FIG. 29. Vertical Journal Bearing

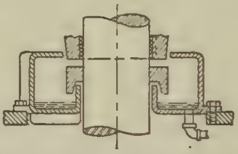

FIG. 30. Collar and Pan for Collecting Oil below a Vertical Journal Bearing.

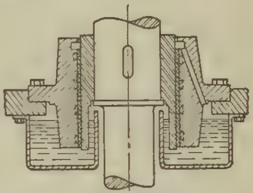

FIG. 31. Lubricating System for Vertical Journal Bearing, Spiral Groove not shown.

**Lubrication of Vertical Journal Bearings.**—With pressure lubrication, the simplest bearing form may be used. The journal surface may be on the shaft itself. To collect the oil flowing down the shaft below the bearing, a collar on the shaft throws the oil into a stationary pan, whence it flows to the sump of the oiling system. See Fig. 30.

Vertical journals may be on the surface of sleeves shrunk or otherwise fastened on the shaft. See Fig. 31. The lower end of the sleeve, which is bored out larger than the shaft projects into the stationary oil pan. Oil may be taken into the bearing film by capillarity, by viscosity pumping, centrifugally, or by combinations of these methods.

If the shaft terminates at the bottom in a vertical journal bearing, lubrication is a relatively simple problem. With a through shaft, simple constructions also may be used, if lubrication is by cup, and if some waste of oil or grease is unimportant. Leakage along the shaft may be minimized by a stuffing-box if the speed of rotation is not so high as to cause heating of the shaft by the packing.

## 2. SHAFT DEFLECTIONS

**DEFLECTION FORMULAS.**—Shaft deflections within journal bearings may be studied by the application of formulas for cantilever beams. The deflection may be considerable, especially when compared to the thickness of the oil film. The basic equation is the general one of the elastic curve

$$(d^2y/dx^2) = M/EI \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [1]$$

where $y$ = deflection at any point at a distance $x$ from the support; $M$ = bending moment at the cross-section under consideration; $E$ = modulus of elasticity of the material; $I$ = moment of inertia of the cross-section, referred to its neutral axis.

Figs. 32 and 33 are two typical arrangements of shaft and bearings, exaggerated to show the relation of the deflected shaft to both rigid and self-aligning bearings. Bearing load may be assumed as concentrated for the purpose of determining shaft deflections and the general direction of its center line in the bearing. To study oil film shape in a self-aligning bearing, or where shaft direction is so little out of line as not to require self-aligning bearings, bearing reaction may be assumed as uniformly distributed. From equation [1], equations [2] to [6] can be derived for the case shown in Fig. 32 which represents a concentrated load. In these equations, $P$ = concentrated load on bearing, and $L$ = distance of point of application of load from point of support, *i.e.*, from the center line of the bearings A and B, other notation as before. The diagrams show the significance of $y_1$.

$$y = (P/EI)\{(Lx^2/2) - (x^3/6)\} \qquad [2]$$
$$dy/dx = (P/EI)\{Lx - (x^2/2)\} \qquad [3]$$
$$y_1 = (L^3/3)(P/EI) \qquad [4]$$
$$dy_1/dx = (L^2/2)(P/EI) \qquad [5]$$
$$y_1 = (2L/3)(dy_1/dx) \qquad [6]$$

For the case shown in Fig. 33*c*, representing a uniformly distributed load, the following equations may be derived, in which $W$ = total uniform load, $\Delta$ = deflection within the bearing, other notation being as before:

$$y = (W/24LEI)\{(L - x)^4 + 4L^3x - L^4\} \qquad [7]$$
$$dy/dx = (W/6LEI)\{L^3 - (L - x)^3\} \qquad [8]$$
$$y_1 = (L^3/8)(W/EI) \qquad [9]$$
$$dy_1/dx = (L^2/6)(W/EI) \qquad [10]$$
$$y_1 = (3L/4)(dy_1/dx) \qquad [11]$$
$$\Delta = (y_1/2) - y \qquad [12]$$

FIG. 32. Shaft with Load between Bearings

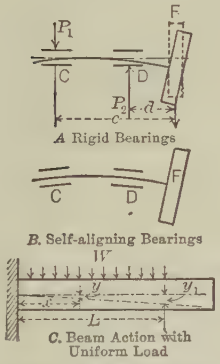

FIG. 33. Shaft with Overhung Load

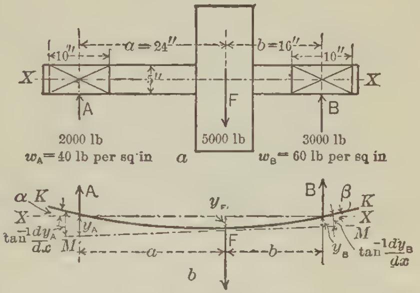

FIG. 34. Data for Solution of Example 1

EXAMPLE 1.—Fig. 34*a* shows a 5-in. shaft, supported in two bearings each 10 in. long, spaced 40 in. center to center. The point of application of load is 24 in. from bearing A and 16 in. from bearing B. It is required to determine the deflection of the shaft, and the angle of the deflected shaft at the bearings with the center line $XX$ through the bearings.

*Solution.*—Reaction of bearing A = 5000 × (16/40) = 2000 lb.; reaction of bearing B = (24/40) × 5000 = 3000 lb. Taking the modulus of elasticity of steel as 30,000,000, and the moment of inertia as $\pi d^4/64 = 30.68$ for a 5-in. shaft, and applying equation [4], the deflections with reference to bearings A and B are:

$$y_A = (24^3/3) \times \{2000/(30{,}000{,}000 \times 30.68)\} = 0.01002$$
$$y_B = (16^3/3) \times \{3000/(30{,}000{,}000 \times 30.68)\} = 0.00446$$

These relations as shown in Fig. 34*b*, in which $XX$ is the center-line of the undeflected shaft, $KK$ is the center-line of the deflected shaft, and $y_A$ and $y_B$, are respectively, the deflections of the shaft at bearings A and B. A line $MM$ drawn through the extremities of $y_A$ and $y_B$ will be tangent to the center-line of the deflected shaft at the point of application of the load F. Its angle with reference to $XX$ will be $\tan^{-1}\{(y_A - y_B)/AB\} = \tan^{-1}\{(0.01002 - 0.00446)/40\} = \tan^{-1} 0.00014$. From equation [5] the direction of the deflected shaft at the bearings is

At bearing A $\quad dy_1/dx_1 = (24^2/2)(2000/30{,}000{,}000 \times 30.68) = 0.000626$

At bearing B $\quad dy_1/dx_1 = (16^2/2)(3000/30{,}000{,}000 \times 30.68) = 0.000417$

These values are the tangents of the angles between the center-line of the deflected shaft at the bearings and the line $MM$, tangent to the shaft at the point of application of load F. In these problems, the angles are so small that the tangents of them can be added and subtracted instead of the angles themselves, without affecting the result. The angles $\alpha$ and $\beta$, respectively, the angles between the center-lines of deflected and undeflected shaft are

$$\tan \alpha = \{(dy_1/dx) - \tan (y_A - y_B/\overline{AB})\} = 0.000626 - 0.00014 = 0.000486$$

$$\tan \beta = \{(dy_1/dx) + \tan (y_A - y_B)/\overline{AB}\} = 0.000417 + 0.00014 = 0.000557$$

Misalignment of the bearings is the product of tan $\alpha$ or tan $\beta$ and the bearing length. Hence, misalignment of bearing A = 10 × 0.000486 = 0.00486 in., and of bearing B = 10 × 0.000557 = 0.00557 in. Since the oil film thickness in the direction of the load in a rigid bearing would be in the neighborhood of 0.002 in., a self-aligning bearing is indicated.

The deflection of the shaft within the bearing length, however, also must be investigated. This may be taken as a case of a uniformly-loaded cantilever beam (see Fig. 35), although the distribution of oil pressure across the film is approximately parabolic for a film of uniform thickness along the axis. Uniformly distributed pressure will show a higher shaft deflection than actual, and thus is on the safe side. Referring to Fig. 35, deflection $y_1$ is found by equation [9], and deflection $y_2$ by equation [7], in which $x$ is taken equal to $L/2$.

In bearing A,

$$y_1 = (10{,}000/8) \times (2000/30{,}000{,}000 \times 30.68) = 0.0002716$$

$$y_2 = (2000/24 \times 30{,}000{,}000 \times 30.68) \times \{(10 - 5)^4 + (4 \times 10^3 \times 5) - 10^4\} = 0.0000961$$

From equation [12] the deflection within the bearing is

$$\Delta = (y_1/2) - y_2 = (0.0002716/2) - 0.0000961 = 0.0000397.$$

By a similar calculation for bearing B, the deflection $\Delta$ = 0.00006.

It should be noted that the deflections above found, although negligible, are proportional to the unit pressures for a given journal. The unit pressures in Example 1, *i.e.*, 40 and 60 lb. per sq. in. are moderate, and much higher pressures may occur with some types of machinery. If heavier loads are applied without suitable compensations in bearing design, the deflections in the shafts and journals may become dangerous.

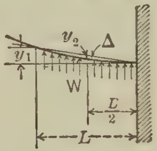

FIG. 35.

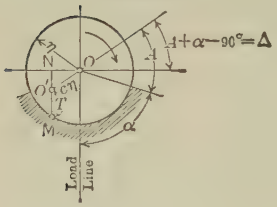

FIG. 36.

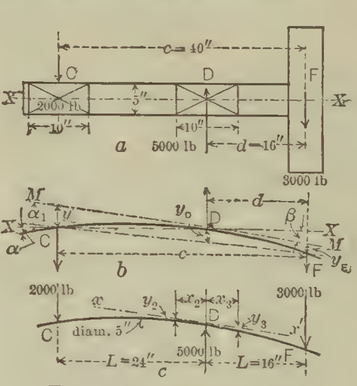

FIG. 37. Data for Example 2

EXAMPLE 2.—Determine the deflections of the shaft of the dimensions and arrangement shown in Fig. 37.

*Solution.*—Draw the axis $MM$ (Fig. 37*b*) tangent to the center line of the deflected shaft at $D$. Compute the deflections $y_C$ = 0.01002 and $y_F$ = 0.00446 by equation [4]. These will be found to be the same as $y_A$ and $y_B$ in Example 1. Determine the angle the deflected shaft, at the bearings, makes with the center-line of the bearings. From equation [5]

$$\tan \alpha_1 = (dy_1/dx) = (24^2/2)\{2000/(30{,}000{,}000 \times 30.68)\} = 0.000626,$$

and $$\tan \beta = y_C/24 = 0.000418.$$

But $$\alpha = \alpha_1 - \beta \therefore \tan \alpha = \tan \alpha_1 - \tan \beta = 0.000626 - 0.000418 = 0.000208.$$

These deflections are too large for the use of fixed bearings, unless the oil films are abnormally thick.

Bearing D, however, must be examined by means of formula [2], and deflections $y_2$ and $y_3$ (Fig. 37*c*) determined. $x_2 = x_3 \doteq 5$; $L_2 = 24$; $L_3 = 16$; $P_2 = 2000$; $P_3 = 3000$.

$$y_2 = (P/EI)\{(Lx_2^2/2) - (x_2^3/6)\} = \{2000/(30 \times 10^6 \times 30.68)\}[\{(24 \times 5^2)/2\} - (5^3/6)] = 0.000607$$

$$y_3 = \{3000/(30 \times 10^6 \times 30.68)\}[\{(16 \times 5^2)/2\} - (5^3/6)] = 0.000584.$$

The unit bearing pressure is $\{5000/(10 \times 5)\}$ = 100 lb. per sq. in., which is permissible, but the deflections within the bearing are sufficient, even with self-alignment, to require a heavy oil for producing a thick enough film.

For a more complete discussion of the methods of determining thickness of oil films, see pp. 13-17 to 13-30.

In calculating shaft deflection in a bearing, the position of the center of the shaft, when running, is important. It shifts to the point $O'$, Fig. 36 within the clearance circle of radius $\eta$. The plane of shaft deflection cuts this circle at $M$, which is the point at which the deflected shaft will make contact with the bearing, assuming that the latter does not deflect. Referring to Fig. 36, the following relations hold: Let $(A + \alpha - 90°) = \Delta$. Then $\overline{ON} = c\,\eta \cos \Delta$; $MN = \sqrt{\eta^2 - \overline{ON}^2}$; $TO' = MN - c\,\eta \sin \Delta$. The deflection should be compared with distance $O'M$, and should not be an unreasonable percentage, say 30%, of $O'M$. The shaft usually should be examined both for strength and stiffness.

## 3. LOADING AND FRICTION OF JOURNAL BEARNGS

**JOURNAL BEARINGS**, for the purpose of study of loading and friction, may be divided broadly into Clearance Bearings and Fitted Bearings. Clearance bearings may be either **full** or **partial bearings.** Fitted bearings invariably are partial bearings. The angular extent to which the useful bearing surface surrounds the journal is designated by $\beta$, and determines whether a bearing is full or partial. In a full bearing $\beta$ = 360 deg.; in a partial bearing $\beta$ usually is less than 180 deg., and averages about 120 deg., except that for fitted bearings it averages about 90 deg.

**Clearance Bearings** are those in which the radius of curvature of the bearing is larger than that of the journal.

**Fitted Bearings** are those in which radius of curvature is the same in both bearing and journal. Values of $\beta$ are essentially less than 180 deg., averaging about 90 deg. Characteristics are given below for such bearings for values of $\beta$ up to 150 deg.

**LOAD DIRECTION.**—Partial bearings may be centrally loaded or eccentrically loaded. There may be different degrees of the latter. The angular extent of bearing surface ahead of the point of load is known as the leading angle $\alpha$. See Figs. 39, 42 and 47.

**Centrally-loaded Bearings** have $\beta$ divided into two equal parts by the line of action of the applied load. That is $\alpha = \beta/2$.

**Eccentrically-loaded Bearings** have $\beta$ divided into two unequal parts by the line of action of the applied load. The ratio $\alpha/\beta$ may vary considerably when bearings are in service, by reason of lack of analysis in design, but some ratios of $\alpha/\beta$ are better than others.

**JOURNAL BEARING CHARACTERISTICS.**—Journal bearings may be divided into six classes as follows, for the purpose of co-ordinating the available analyses: A. Eccentrically loaded partial bearings with running clearance. See Fig. 39. B. Fitted partial bearings, Fig. 43. C. Centrally loaded partial bearings with running clearance, Fig. 47. D. Offset partial bearings with running clearance, Fig. 39. E. Fitted partial bearings, Fig. 43, with variable ratio of $\alpha/\beta$. F. Full bearing with running clearance, Fig. 55. The characteristics of these several types of bearings are discussed below. Classes B, D and E all are eccentrically loaded and different in some respects. For Classes A, B and C, Kingsbury's optimum conditions are given in the charts. For Classes C, D, E, and F, Howarth's charts for general conditions are given. Classes A and D are similar, but not quite alike. The same is true of Classes B and E. In chart Fig. 56, general conditions of loading are given for a wide variety of 120-deg. clearance bearings including those of Classes A, C, and D.

**Notation.**—In the discussion which follows, the significance of the symbols used is given below. Unless otherwise specified in the text, all linear dimensions are in inches, and forces (loads) are in pounds.

$a$ = radius of journal.
$A$ = least angle from line of centers to leading edge of partial bearing, measured in direction of rotation. See exception in study of fitted bearings, Fig. 43, p. 13–20.
$b$ = width of bearing surface measured along the shaft axis in a journal bearing, or, in general, at right angles to direction of motion.
$c$ = eccentricity factor. When multiplied by the radial clearance $\eta$, the product $c\eta$ equals distance from center of bearing to center of journal.
$F$ = total tangential friction force at surface of a journal, or at mean diameter of a thrust bearing, per unit of width of bearing surface.
$F_1$ = correction factor for friction, *with side leakage.*
$h$ = film thickness at any angular position $\theta$ in journal bearings, or any distance $x$ for flat tapered film. For fitted journal bearings $h = \epsilon \sin \theta$, and for clearance journal bearings $h = \eta(1 + c \cos \theta)$.
$h_o$ = minimum thickness of oil film in a bearing, usually. When the line of centers for a clearance bearing does not intersect the partial bearing surface, $h_o$ is measured where the bearing surface, if extended, would cross that line.
$h_1$ = thickness of oil film at region of maximum pressure.
$h_A$ = thickness of oil film at entering edge of bearing film, if less than $h_m$.
$h_E$ = film thickness at trailing edge of partial clearance bearing, when greater or less than $h_o$.

$h_m$ = maximum thickness of oil film.

$H$ = horsepower friction developed by a journal bearing, or thrust bearing, per unit of bearing width.

Hp. = horsepower.

$l$ = length of a bearing face in the direction of motion. In a partial journal bearing, whose angular extent $\beta$ is expressed in degrees, $l = \pi\beta a/180$. This is useful for determining length-width ratio, $l/b$, used in selecting side leakage correction factors.

$L_1$ = correction factor for load carrying capacity, *with side leakage.*

$N$ = revolutions per minute.

$n$ = number of pivoted segments in a thrust bearing.

$O$ = center of curvature of journal when running on oil film.

$O'$ = center of curvature of bearing surface supporting journal.

$p$ = pressure within the oil film where the thickness is $h$.

$p_o$ = nominal mean pressure acting on bearing. In journal bearings, $p_o$ is found by dividing total applied load by (journal diameter × axial bearing width). It also is expressed by $W/2a$. $W$ is taken per unit of width. In thrust bearings, $p_o = R/n\,l\,b$. See Fig. 82.

$P_m$ or $P_{\text{max.}}$ = maximum pressure within oil film of a bearing.

$R$ = total load applied by a journal to a bearing, or by a collar to a thrust bearing.

$R'$ = total reaction of bearing against the journal.

$s$ = a film form dimension in Fig. 91, which see.

$U$ = relative velocity of the bearing surfaces (usually in. per sec.). In thrust bearings it is measured on the mean diameter.

$V$ = relative velocity of bearing surfaces, ft. per min.

$w$ = nominal mean unit load a bearing would carry if side leakage could be neglected. See $p_o$. The relation is $p_o = L_1 w$.

$W$ = actual load applied by a journal to its bearing, per unit of axial width = $R/b$.

$Z$ = character expressing viscosity coefficient in centipoises. See $\mu$.

$\alpha$ = leading angle for partial bearing, measured in direction of motion of journal from leading edge of bearing to line of action of load.

$\beta$ = angular extent of bearing surface over which perfect film lubrication is maintained. Usually expressed in degrees.

$\epsilon$ = eccentricity of journal axis when running in a fitted bearing.

$\eta$ = radial clearance provided in a clearance bearing. When $a$ = journal radius, $(a + \eta)$ = radius of curvature of a bearing surface, and $c\eta$ = eccentricity of running position of journal axis in a clearance bearing.

$\theta$ = angle from reference diameter to point within oil film where thickness is $h$.

$\theta_1$ = angle $\theta$ corresponding with location of maximum unit pressure within the oil film.

$\lambda$ = coefficient of friction for journal surface. In thrust bearings, $\lambda$ is the coefficient for mean diameter of thrust collar face. $\lambda = (F_1/L_1)\lambda_H$.

$\lambda'$ = coefficient of friction for bearing surface.

$\lambda_H$ = uncorrected coefficient of journal friction in charts.

$\mu$ = coefficient of viscosity. When not otherwise specified, $\mu$ is expressed in lb.-sec. per sq. in. (Reyns). The term *Reyn* is applied to the coefficient when expressed in English units. The c.g.s. unit for $\mu$ is the *Poise* measured in dyne-seconds per sq. cm. One poise = 0.000 0145 Reyn; 1 Reyn = 69,000 poises.

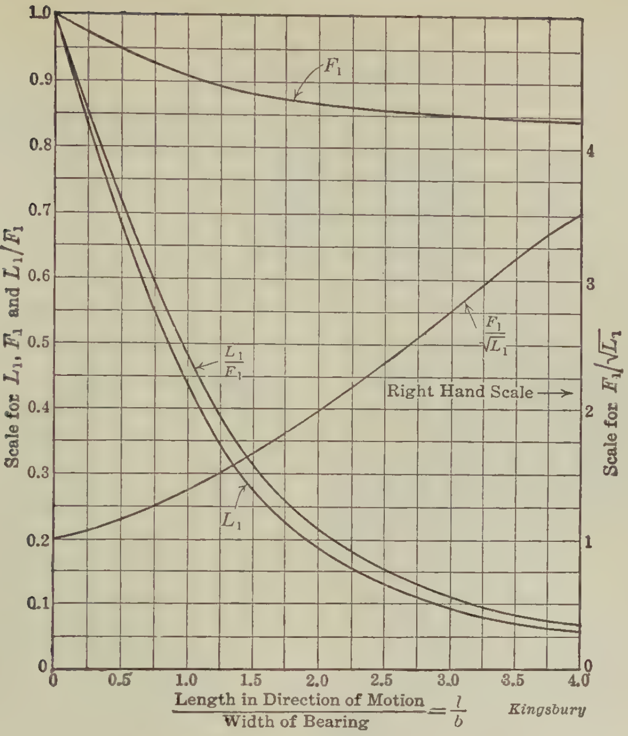
$\phi$ = angle relating load line to line of centers of journal and bearing in Kingsbury's optimum condition (see p. 13–29). See also bearing cross-sections, Figs. 39, 43 and 47.

$\phi_H$ = angle relating load line to line of centers of journal and bearing in bearing cross-sections in Figs. 51 to 56.

**CORRECTION FOR SIDE LEAKAGE.**—Side leakage has an important influence on load capacity and friction of journal bearings. If this influence be neglected in the solution of bearing problems, the data of the charts, Figs. 40 to 56, will not agree well with actual conditions, and side leakage factors, therefore, must be included in the bearing problem data. Fig. 38 gives factors applying to optimum film proportions, but which are fairly dependable when applied to conditions not too far different from optimum. These are the best generally applicable data available (1937) for side leakage corrections. When applied to abnormal conditions, they tend to bring results toward correct values, and usually are on the safe side.

Fig. 38 is used as follows: In the dynamical tables and curves following which apply to the various classes of bearings, as enumerated above, numerical coefficients are for infinitely wide conditions, under which side leakage is zero. For bearings of finite width and a given ratio of (length/width) the numerical coefficients are to be multiplied by a correction factor from Fig. 38. The proper correction curve in Fig. 38 to use for the various symbols or symbol groups of the dynamical tables and curves is as follows:

| | | | | | | | |
|---|---|---|---|---|---|---|---|
| Symbol Group................ | $W$ | $F$ | $\lambda$ or $F/W$ | $H$ | $H/W$ | $W/H$ | $\lambda/\sqrt{\mu N/p_o}$ |
| Correction Factor............ | $L_1$ | $F_1$ | $F_1/L_1$ | $F_1$ | $F_1/L_1$ | $L_1/F_1$ | $F_1/\sqrt{L_1}$ |



*Kingsbury*

FIG. 38. Correction Factors for Influence of Side Leakage upon Load-carrying Capacity and Friction

**CHARTS FOR DETERMINATION OF BEARING PROPORTIONS.**—The charts, Figs. 42, 46 and 50 give data useful in the design of optimum bearings of classes A, B, and C respectively. They show the relation of proportion, dimensions, power loss, film thickness, speed and load for a variety of conditions with each type. Total load $R$ on the bearing, and speed, usually are the known factors, and the minimum thickness of the oil film $h_o$ may be assumed. (See examples below.) The permissible loading of the bearing $p_o$ also may be assumed. The projected area of the bearing then is $R/p_o$; it also is $2a^2\ (b/a)$. The ratio of width to radius of journal *i.e.*, $b/a$, when decided, may be substituted in $2a^2\ (b/a)$. By equating the two expressions for projected area, the value of $a$ can be determined. Then from $R$ and $b$ the value of $W$ is obtained.

In Figs. 42, 46 and 50, the power loss for any ratio of $b/a$ at any angular contact $\beta$ can be found by reading on the appropriate curve. The minimum power loss is at the point of inflection of the curve, but does not include any losses in clearance spaces outside of the arc of angular contact $\beta$.

**A. Eccentrically-loaded Partial Bearings with Running Clearance** (Fig. 39).—The radius of curvature of the bearing is greater than that of the journal. The line of application of the load does not pass through the center of the bearing arc, and $\alpha > \beta/2$. The optimum condition for best ratio of $\alpha/\beta$ for values of $\beta$ from 0 to 360 deg. are given in Figs. 40–42 and Tables 3 and 4. Their use is best shown by an example.

EXAMPLE 1.—Determine the proportions of a bearing of minimum friction to support a load of 25,000 lb. at 1500 r.p.m. with $h_o = 0.003$ in., with a pressure of 200 lb. per sq. in. of projected area.

*Solution.*—Projected area = 25,000/200 = 125 sq. in. = $2a^2(b/a)$. Assume $b/a = 3$, whence $a = \sqrt{(125/6)} = 4.564$ in. This value should be checked for strength in bending and in torsion.

From the curve $b/a = 3$ in Fig. 42, the minimum power loss $H$ per unit of width $b$ occurs with a value of $\beta = 153.6$ deg. = 2.68 radians, corresponding to a value of $WNh_o/H = 16{,}900$, whence

$$\text{Total power loss } (H \times b) = 25{,}000 \times 1500 \times 0.003/16{,}900 = 6.66 \text{ Hp.}$$

This figure does not include losses in any clearance spaces outside of the arc of contact $\beta$.

This chart shows values of non-dimensional group $(W\,N\,h_o/H)$ as affected by side leakage, with film forms for minimum coefficient of friction. Curve *J* gives values of $b/a$ at which group $(W\,N\,h_o/H)$ is greatest for each value of $\beta$. See Figs. 40 and 41 and Tables 3 and 4 for optimum conditions, assuming constant viscosity and no side leakage. When a curve for a given ratio of $b/a$ is chosen, each ordinate of it will be correct for the optimum relation of the symbols in this group. Hence the correction factors for side leakage are already allowed for in the heights of those ordinates.

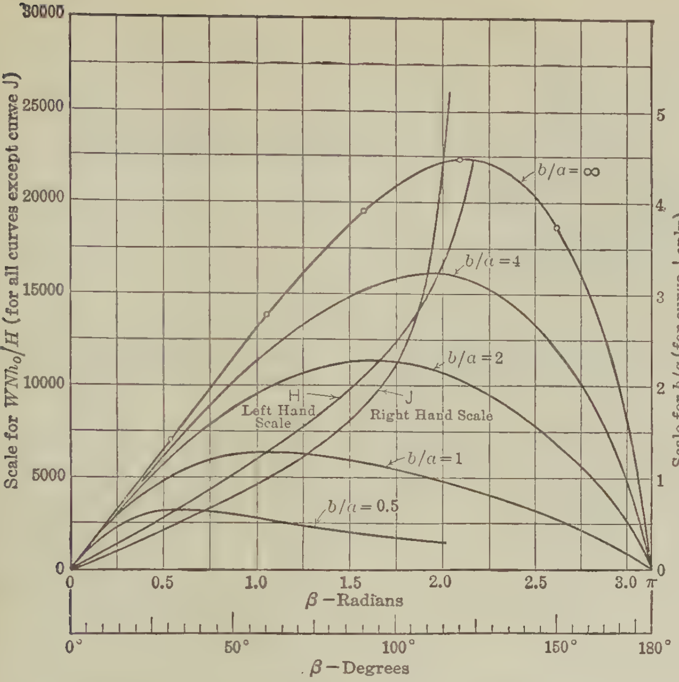

FIG. 46. Side Leakage Chart for Class B Journal Bearings for Minimum Friction Coefficients. See Fig. 43.

This chart shows values of the non-dimensional group ($W\ N\ h_o/H$) as affected by side leakage with film forms for the minimum coefficient of friction. Curve *J* gives the value of $b/a$ at which group ($W\ N\ h_o/H$) is greatest for each value of $\beta$. See Figs. 44 and 45 and Tables 5 and 6 for optimum conditions, assuming constant viscosity and no side leakage. When the curve for a given ratio of $b/a$ is chosen, each ordinate of it will be correct for the optimum relation of the symbols in this group. Hence the correction factors for side leakage are already allowed for in the heights of those ordinates.

FIG. 50. Side Leakage Chart for Class C Clearance Bearings, for Minimum Friction Coefficients. See Fig. 47.

This chart shows the values of the non-dimensional group $(W\,N\,h_o/H)$ as affected by side leakage with film forms for the minimum coefficient of friction. Curve *J* gives the value of $b/a$ at which group $(W\,N\,h_o/H)$ is greatest for each value of $\beta$. See Figs. 48 and 49 and Tables 7 and 8 for optimum conditions, assuming constant viscosity and no side leakage. When the curve for a given ratio of $b/a$ is chosen, each ordinate of it will be correct for the optimum relation of the symbols in this group. Hence the correction factors for side leakage are already allowed for in the heights of those ordinates.

*(Continued from p. 13-17)*

Clearance $\eta$ is determined as follows: The ratio of $\eta/h_o$ is found from curve 7, Fig. 40, to be 1.72, corresponding to $\beta = 153.6$, when $\eta = 1.72\ h_o = 1.72 \times 0.003 = 0.00516$ in.

Bore diameter of bearing $= 2(a + \eta) = 2(4.564 + 0.00516) = 9.138$.

Clearance ratio $\eta/a = 0.00516/4.564 = 0.00113$.

To ascertain required oil viscosity coefficient, correction factors must be determined by means of Fig. 38. Arc length of bearing surface $l = \beta$ (radians) $\times\ a = 2.68 \times 4.564 = 12.23$ in. Width $b = (b/a) \times 4.564 = 13.69$, and $l/b = 0.893$. At the points on the several curves in Fig. 38 corresponding to $l/b = 0.893$, the following correction factors are found: $L_1 = 0.487$; $F_1 = 0.916$; $L_1/F_1 = 0.532$. To ascertain the mean viscosity in the oil film, refer to group 10 and curve 10, Table 4 and Fig. 41. For an infinitely wide bearing and $\beta = 153.6$, curve 10 shows the value of $W(h_o^2/\mu Na^3)$ to be 0.117. Applying the correction factor, $W(h_o^2/\mu Na^3)$, $L_1 = 0.117 \times 0.487 = 0.05698$. The actual mean load per unit width of bearing is $W = 25{,}000/13.69 = 1826$ lb. Substituting this and other known values in group 10, we find

$\mu = (1826 \times 0.003^2)/(0.05698 \times 1500 \times 4.564^3) = 2.022 \times 10^{-6}$ Reyn.

$= 69{,}000 \times 2.002 \times 10^{-6} = 0.1395$ poise, corresponding to a light machinery oil at 130° to 140° F. For corresponding commercial viscosities, see p. 13-55.

The coefficient of friction $\lambda$ is found by means of curve 12 and group 12, Fig. 41, and Table 4. Let $m$ = the value on curve 12 corresponding to value of $\beta$. In the present case, $\beta = 153.6$, whence $m = 2.00$. Then

$$\lambda = (F_1/L_1) \times m \times (h_o/a) = (2.00 \times 0.003)/(0.532 \times 4.564) = 0.00247.$$

Inspection of Fig. 42 shows that, other things being equal, an increase of the ratio $b/a$ will reduce the relative power loss. See Example 2. The possible increase in $b/a$ is limited by considerations of space, cost, and strength or elasticity of the journal. In Example 1, $\beta$ might be increased, following the curve $b/a = 3$, Fig. 42, to obtain a greater bearing area, with, however, a relatively greater friction loss. Other data for the bearing in question can be found from Figs. 40 and 41, and Tables 3 and 4; for example, leading angle $\alpha$ from group 3 and curve 3.

EXAMPLE 2.—Assume the same data as for Example 1, excepting that $b/a = 4$. Then using the same curves and tables we have,

$a = \sqrt{125/8} = 3.953$ in.; $\beta = 180.8$ deg. $= 3.155$ radians for least power loss.
Total power loss $= (25{,}000 \times 1500 \times 0.003)/20{,}700 = 5.435$ Hp.
Clearance $\eta = 1.622\ h_o = 0.004866$ in., $= 0.00123$ in. per inch of diameter.
Length $l = 3.155 \times 3.953 = 12.47$ in. Width $b = 4 \times 3.953 = 15.81$ in.
Ratio $l/b = 0.789$. This determines the correction factors:
$L_1 = 0.533$; $F_1 = 0.924$; $L_1/F_1 = 0.577$.
$W = 25{,}000/15.8 = 1581$ lb.
$\mu = (1581 \times 0.003^2)/(0.1517 \times 0.533 \times 1500 \times 3.953^3) = 1.90 \times 10^{-6}$ Reyn, corresponding to 0.131 poise.
$\lambda = (F_1/L_1) \times m \times (h_o/a) = (1.762 \times 0.003)/(0.577 \times 3.953) = 0.002318$.

The charts and tables also may be used to determine proper radial clearance or oil viscosity for a known set of other conditions. See Example 3.

**B. Fitted Partial Bearings** (Fig. 43).—The journal and bearing have the same radius of curvature. The line of application of the load does not pass through the center of the bearing arc, and $\alpha > \beta/2$. Figs. 44 and 45 and Tables 5 and 6 show optimum conditions for values of $\beta$ from 0 to 150 deg. The procedure followed in design is the same as that for Class A bearings, except that reference is made to the tables and curves for Class B bearings corresponding to those used for Class A bearings in Examples 1 and 2. See also Example 5.

**C. Centrally-loaded Partial Bearings with Running Clearance** (Fig. 47).—The radius of curvature of the bearing is greater than that of the journal. The line of application of the load passes through the center of the bearing arc, and $\alpha = \beta/2$. Figs. 48 to 50 and Tables 7 and 8 show optimum conditions for values of $\beta$ from 0 to 180 deg. Fig. 51 shows general conditions for values of $\beta$ from 60 to 180 deg. Bearing problems may be solved by the same procedure as used for Examples 1 and 2 except that reference should be made to the curves and tables of Class C bearings. Example 3 shows the application of the curves to the selection of the correct radial clearance $\eta$.

EXAMPLE 3.—Determine the best radial clearance $\eta$ for a bearing in which the total load $R =$ 25,000 lb., $N = 1500$ r.p.m., $\beta = 120$ deg., $p_o = 125$ lb. per sq. in., ratio of width to radius, $b/a = 4$, oil viscosity, $\mu = 3.4 \times 10^{-6}$ Reyn.* Bearing is centrally loaded.

*Solution.*—By procedure outlined in Example 1 and from the foregoing data, $2a = 10$ in., $b =$ 20 in., $W = 1250$, $l = 10.47$ in., $l/b = 0.524$.

Correction factors from Fig. 38 will be $L_1 = 0.672$, $F_1 = 0.947$, $L_1/F_1 = 0.710$. Then from group 10 in Table 8, by introducing correction factor $L_1$, we have $Wh_o^2/\mu Na^3 = 0.0672\ L_1 = 0.0451$. Substituting the known values in this equation, and solving for $h_o$, we find $h_o = 0.0048$. In group 7, Table 8, the value of $\eta/h_o$ for $\beta = 120$ deg. is 1.962, whence $\eta = 1.962 \times h_o = 1.962 \times 0.0048 =$ 0.0094. Clearance ratio $= \eta/a = 0.0094/5 = 0.00188$. Friction coefficient factor $\lambda a/h_o$ is found

---

* See Viscosity-temperature conversion chart, p. 13-56, to obtain corresponding commercial viscosities.

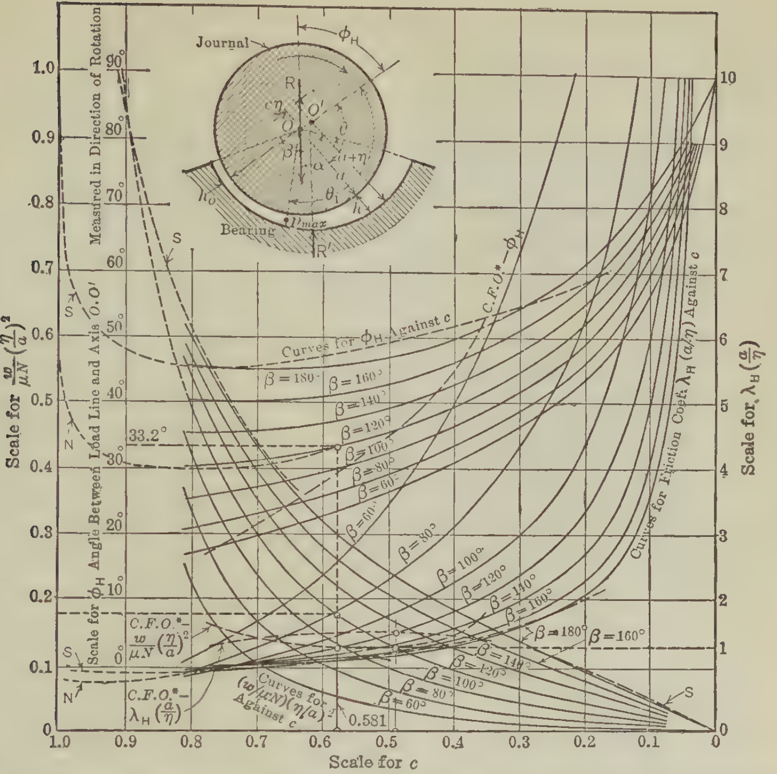

FIG. 51. General Characteristics of Centrally-loaded Clearance Bearings, Class C,† assuming constant velocity and no side leakage

C. F. O. = Class C friction optima. Where the dotted curves cut the corresponding full line curves the values are identical with the optimum conditions for minimum friction coefficient in Figs. 48 and 49 and Table 8.

from group 12, Table 8 to be 2.902, to which the correction factor $L_1/F_1$ must be applied. Hence,

$$\lambda = (h_o/a) \times 2.902 \times \{1/(L_1/F_1)\} = (0.0048/5) \times 2.902 \times (1/0.710) = 0.00392.$$

For conditions other than optimum the charts Figs. 51 to 56 may be used. The side leakage correction factors given in Fig. 38 may be applied to these curves with fair approximation. See Example 4.

EXAMPLE 4.—Given a centrally-loaded 120-deg. bearing with a total load $R$ = 10,000 lb., and actual nominal pressure $p_o$ = 125 lb. per sq. in. Journal diameter is 8 in. and bearing width is 10 in. Clearance ratio $\eta/a = 0.001$, and speed $N$ = 400 r.p.m. Determine the running position of the journal when using two oils of viscosity coefficient $\mu = 3.4 \times 10^{-6}$ Reyn, and $10.2 \times 10^{-6}$ Reyn, respectively.

*Solution.*—Referring to Fig. 51, the scale at the left represents a symbol group in which all values are known except $w$, which is the ideal nominal unit pressure that the bearing would sustain if side leakage could be neglected. This ideal pressure is reduced to actual pressure $p_o$ by side leakage, and $p_o = L_1 w$. Correction factor $L_1$ is found from Fig. 38. The ratio $l/b = \{(120/360)\pi 8\}/10 = 0.839$. Entering Fig. 38 at $l/b = 0.839$, the correction factors are found to be as follows: $L_1 = 0.51$; $L_1/F_1 = 0.555$; $F_1 = 0.92$. Then $W = 125/0.51 = 245$, and

$$(w/\mu N)(\eta/a)^2 = (245 \times 1 \times 10^{-6})/(\mu \times 400) = (0.613 \times 10^{-6})/\mu.$$

---

[*] Curve C. F. O. – $(w/\mu N)\,(\eta/a)^2$ is the locus for the loading that is proper for these optima for various values of $\beta$. Curve C. F. O. – $\lambda_H(a/\eta)$ is the locus of the corresponding friction coefficients. Curve C. F. O. – $\phi_H$ is the locus of the angles that determine the journal running positions. The three points for each angle $\beta$ are on a vertical line through the corresponding eccentricity factor on the base scale, as for example the point marked for $c$ = 0.49 and $\beta$ = 120°.

[†] This chart has been adapted from earlier one by Howarth (7) and contains added curves and points obtained from the work of other investigators. For dotted curves $S$, see Sommerfeld (14). For dotted curves $N$, see Needs (15). For dotted curves, marked C. F. O., see Kingsbury (5). These numbers refer to the bibliography, p. 13–58.

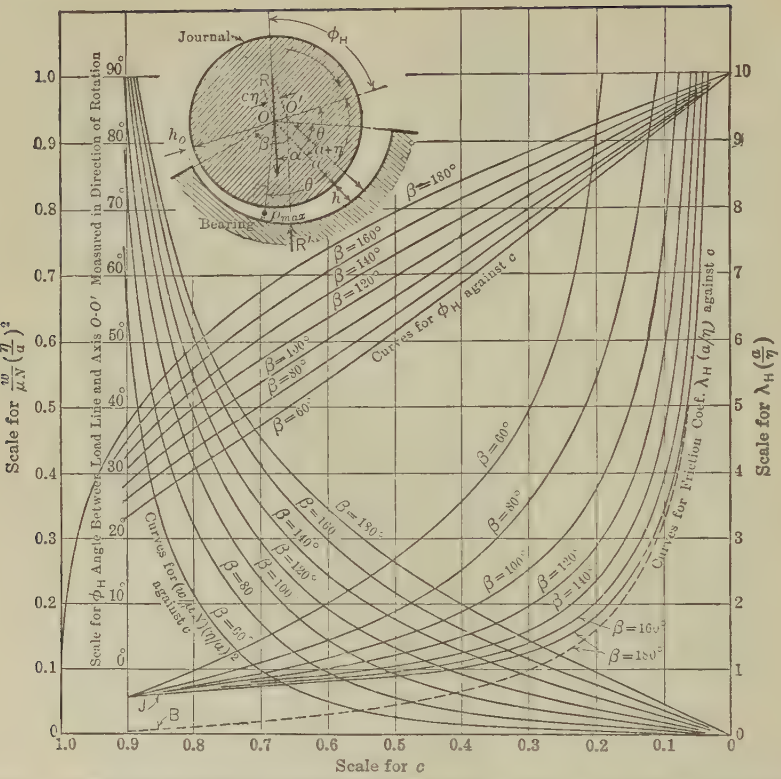

FIG. 52. General Characteristics of Offset Clearance Bearings, Class D, Assuming Constant Viscosity and No Side Leakage. See Fig. 53 for Corresponding Ratios of $\alpha/\beta$.

This class of bearings differs somewhat from the eccentrically-loaded bearings in Class A.

The next step is to substitute in the above expression the two values of $\mu$ given in the statement of the problem, and with the resulting values enter Fig. 51 at the left. First substituting $\mu = 3.4 \times 10^{-6}$, $(w/\mu N)(\eta/a)^2 = 0.180$. Locating this point on the load-capacity curve, $\beta = 120$ deg. (the group of curves starting at the lower right) find $c = 0.581$. The ordinate of $c = 0.581$ intersects the friction coefficient curve for $\beta = 120$ deg. (group of curves starting at the lower left) at $\lambda_H a/\eta = 1.29$. This ordinate also intersects the $\phi_H$ curve (group of curves starting at the upper right) for $\beta = 120$ deg. at $\phi_H = 33.2$ deg.

The actual friction coefficient will be $\lambda = (F_1/L_1)\lambda_H = 1.29 \times 10^{-3}/0.555 = 0.00233$.

The journal running position will be on the line $\phi_H = 33.2$ deg. and its distance from the center of the bearing will be $c\eta = 0.581 \times (8/2) \times 0.001 = 0.002324$ in. The minimum film thickness will be $h_o = (1 - c)\eta = 0.001676$ in. Optimum eccentricity is shown by the dotted C. F. O. loading curve $(w/\mu N)(\eta/a)^2$ to be 0.49 for a 120-deg. bearing, with a corresponding value of $h_o = 0.00204$. Hence, with $\mu = 3.4 \times 10^{-6}$, this bearing is not quite so safe as the optimum would be.

Solving the problem with $\mu = 10.2 \times 10^{-6}$, the value of $(w/\mu N)(\eta/a)^2$ for entering the chart is 0.060. The following values then are established:

$$c = 0.28;\ \phi_H = 46 \text{ deg.};\ \lambda_H a/\eta = 2.54;\ \lambda = 0.00458;\ h_o = 0.00288.$$

Friction and minimum film thickness are greater with the heavier oil. An intermediate oil would cause the journal to run with optimum eccentricity. The decision then rests on which of the three oil film thicknesses $h_o$ = 0.00168, 0.00204, or 0.00288 in. best suits the required shaft alignment and other conditions. Heavier oil is best where shaft alignment conditions are not ideal. See Shaft Deflections, p. 13–12, and also the film thickness noted in Table 11.

**D. Offset Partial Bearings with Running Clearance.**—These are eccentrically loaded bearings that differ somewhat from the eccentrically loaded partial bearings of Class A. The line of application of the load does not pass through the center of the bearing arc and

$\alpha > \beta/2$. The relation of journal and bearing is shown in the inset in Fig. 52. In this series a particular value of $\alpha/\beta$ refers to each value of $\beta$ and each running position (eccentricity). The characteristics of a bearing with a given value of $\beta$ and $\alpha/\beta$ ratio are shown by one point only on Fig. 53 and by another on Fig. 52, but are not available for a combination of $\beta$ and $\alpha/\beta$ throughout any range of running positions. If on the other hand, entry is made through Fig. 52, in the same manner as explained in Example 4, and a suitable eccentricity is determined, Fig. 53 will give the corresponding ratio of $\alpha/\beta$. Side leakage corrections may be applied as in Example 4. If the useful film has an angular length $\beta$ that is less than the film space provided, or if the angle $\beta$, whether constant or variable with eccentricity, changes its $\alpha/\beta$ ratio with change of eccentricity, Fig. 52 will prove useful for comparing theory with actual practice.

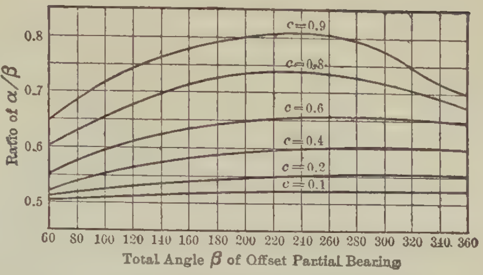

FIG. 53. $\alpha/\beta$ Values of Class D Journal Bearings. For other characteristics, see Fig. 52.

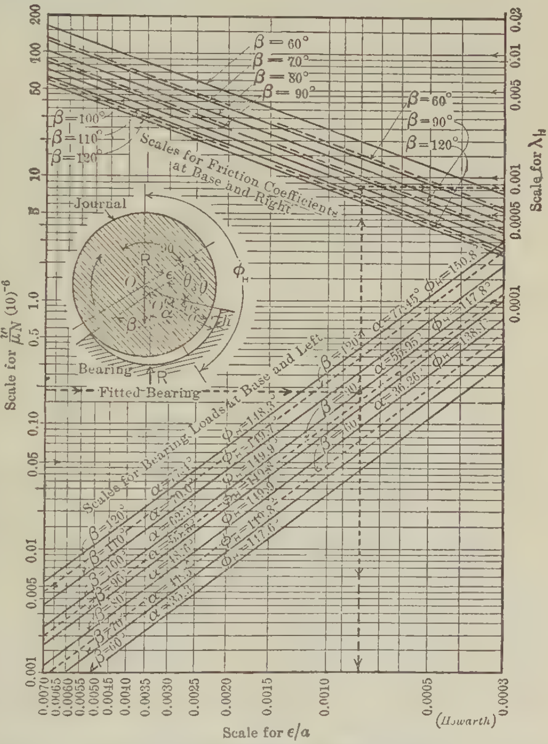

(Howarth)

FIG. 54. General Characteristics of Fitted Bearings, Class E. This series differs slightly from Class B as indicated by the broken lines for $\beta$ = 60 deg., $\beta$ = 90 deg., and $\beta$ = 120 deg., which represent the optima for minimum friction coefficient.

**E. Fitted Partial Bearings.**—The radius of curvature of the bearing is the same as that of the journal. The line of application of the load does not pass through the center of the bearing arc, and $\alpha > \beta/2$. The relations of bearing and journal are shown in the inset in Fig. 54. Bearings of this class differ slightly from Class B bearings. In Fig. 54, which gives general conditions for a definite series having variable $\alpha/\beta$ ratios with values of $\beta$ from 60 to 120 deg., the nearest equivalent to a clearance ratio is the scale $\epsilon/a$, in which $\epsilon$ is the actual eccentricity of the running position of the journal. Angle $\phi_H$, marked on the diagonal for the loading of the particular bearing of angle $\beta$ that is under consideration, shows the direction of shift of the journal center. See Example 5.

EXAMPLE 5.—Given a 100-deg. fitted bearing of journal diameter 5 in., and width 6 in., carrying a total load $R$ of 3000 lb., running at $N$ = 300 r.p.m., and using oil of viscosity $\mu = 3 \times 10^{-6}$ Reyn. Find the minimum film thickness.

*Solution.*—$l/b = (5\pi/6) \times (100/360) = 0.727$, from which (see Fig. 38) $L_1 = 0.565$, and $w = 3000/(6 \times 5 \times 0.565) = 177$. Then $(w/\mu N) \times 10^{-6} = (177 \times 10^{-6})/(3 \times 10^{-6} \times 300) = 0.197$, which value is used to enter Fig. 54. The intersection of this value with the lower diagonal $\beta$ = 100, gives a value of $\epsilon/a$ of 0.0008. The minimum thickness of oil film $h_o$ will be at the trailing edge of the bearing, and is, numerically, $h_o = \epsilon \sin \theta$. From inset in Fig. 54, $\theta = 270° + \beta - (\phi_H + \alpha) = 157.6°$. Hence $h_o = 0.0008 \times 2.5 \times 0.381 = 0.00076$.

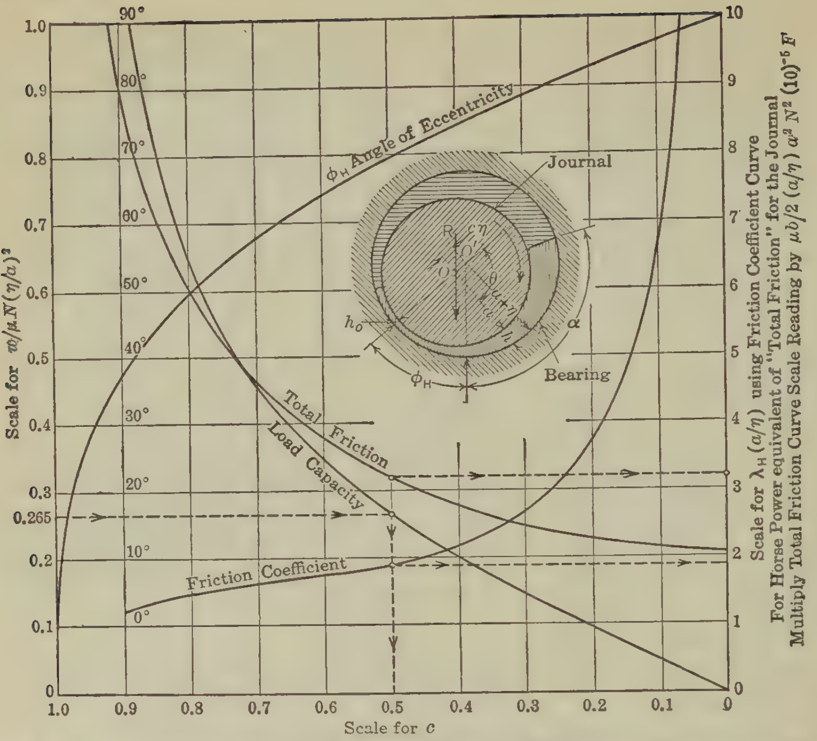

FIG. 55. General Characteristics of Full Bearings, Class F, with Running Clearance, Assuming Constant Viscosity and No Side Leakage.*

Other data that may be obtained from Fig. 54 are: Uncorrected coefficient of friction $\lambda_H = 0.00082$. Applying correction factor $L_1/F_1 = 0.61$ (Fig. 38), the actual coefficient of friction

$$\lambda = \lambda_H/(L_1/F_1) = 0.00082/0.61 = 0.00134.$$

**F. Full Bearings with Running Clearance.**—This bearing which is shown in the inset in Fig. 55 is treated as a half-bearing so far as carrying capacity and running position are concerned. As regards friction, it is treated as a full bearing in which the running position of the journal is the same as for a half-bearing. The line of application of the load, when the film is in running position would not pass through the center of the supporting film arc. The useful film of the bearing, therefore, may be treated as that of an offset bearing, Class D. In Fig. 55, the load capacity curve is taken from Fig. 52 for $\beta = 180$ deg., Class D bearings. The pressure film in full bearing is not apt to exceed 180 deg. in angular extent. The experiments of Stanton (16), Bradford (17), and McKee (18)† indicate shorter films for certain conditions. For other arcs than 180 deg., the appropriate curve for load capacity in Fig. 52 can be used to find the eccentricity. Fig. 55 then can be entered with the eccentricity so found, the approximate total friction determined and the horsepower loss estimated. The friction coefficient curve in Fig. 55 can be used only with the load capacity curve in the same illustration. Example 6 shows the use of side leakage correction factors in a full bearing.

EXAMPLE 6.—Determine the friction power loss and friction coefficient of a full bearing of diameter $2a = 4$ in., width $b = 8$ in., running at $N = 3600$ r.p.m., and carrying a total journal load $R = 3600$ lb. The clearance ratio $\eta/a = 0.003$, and the oil viscosity $\mu = 2 \times 10^{-6}$ Reyn.

*Solution.*—In order to find $L_1$, assume $\beta = 180$ deg. Then $l/b = (4\pi/8) \times (180/360) = 0.79$, and from Fig. 38 $L_1 = 0.53$. $F_1 = 0.925$, and $L_1/F_1 = 0.575$.

$$w = R/(2a \times b \times L_1) = 3600/(4 \times 8 \times 0.53) = 212 \text{ lb. per sq. in.}$$

---

* The load capacity curve corresponds to that for an offset (Class D) bearing for which $\beta = 180$ deg. (See explanations on page 13–26.) The friction curves assume that for the purpose of calculating this loss the bearing film may be considered as extending all around the journal. This assumption is arbitrary but appears to be well on the safe side.

† See Bibliography, p. 13–58.

Fig. 55 is entered with the value of the symbol group

$$(w/\mu N)(\eta/a)^2 = (212 \times 9 \times 10^{-6})/(2 \times 10^{-6} \times 3600) = 0.265.$$

This value on the load capacity curve corresponds to a value of eccentricity factor $c = 0.5$. For this value of $c$ the value of $\lambda_H a/\eta$ is read from the friction coefficient curve as 1.88. The total friction factor is read from the total friction curve as 3.2.

$$\text{Total power loss} = \text{Total friction factor} \times (\mu b/2)(a/\eta)a^2 F_1 N^2 \times 10^{-5} = 4.1 \text{ Hp.}$$

$$\text{Actual coefficient of friction } \lambda = \lambda_H/(L_1/F_1) = \lambda_H/0.583 = 0.0098.$$

Checking back $\lambda_H$ to the total power loss, the latter is found to be the same if the correction factor is properly introduced in $\lambda = (F_1/L_1)\lambda_H$.

**GENERAL CHARACTERISTICS OF JOURNAL BEARINGS.**—Fig. 57 may be used to study the influence on running position, in all classes of 120-deg. clearance bearings, of such changes in design proportions as the $(\alpha/\beta)$ ratio, and the clearance ratio $(\eta/a)$. Side leakage correction factors may be applied as in Example 4, but only for $L_1$ as in $p_0 = w\, L_1$. The reliability of factor $L_1$, decreases with increased departure from good film proportions. Kingsbury's optimum points for maximum load and minimum friction for Class A bearings are designated by ALO and AFO, respectively. Similar maximum load and minimum friction points for Class C bearings are designated by CLO and CFO, respectively. These points permit the determination of the deviation from optimum of the actual conditions in a given bearing. Fig. 57 also gives the angular location, $\theta_1$, of the maximum film pressure. These curves may be used to determine whether there is a possibility of negative pressures existing in the oil film. All pressures in the film are positive between the lines $M$ and $N$. An unpublished investigation by S. J. Needs shows that negative pressure is to be expected in a finite bearing where the bearing of infinite width would show all pressures to be positive. Hence, when the data of a problem show that the running position approaches the upper limit line of Fig. 57, some negative pressure is probable. If such conditions exist, it is advisable to place the problem in some other class of bearing, using $\alpha = 60$ deg. as suggested below.

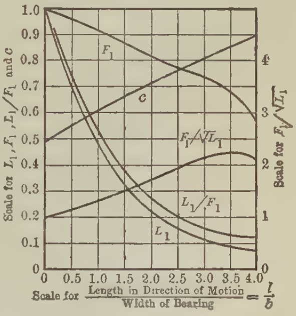

Fig. 56. Correction Factors for Influence of Side Leakage on Load Carrying Capacity and Friction for 120-deg. Class C Journal Bearing. See Fig. 38.

S. J. Needs has determined (15), for 120-deg. centrally-loaded bearings, the optimum eccentricities and the correction factors, for length-width ratios up to 4.0. His results are best shown in Fig. 56 which is in a form comparable with Kingsbury's chart, Fig. 38. The eccentricity for optimum friction condition is shown to vary from 0.49 for $l/b = 0$, to 0.90 for $l/b = 4.0$, with approximately straight line interpolation between. He further concludes that side leakage factors depend on bearing loads as well as length-width ratios, and that the length-width ratio influences the eccentricity for optimum operating conditions. See discussion in the paper referred to.

If conditions of operation are such that negative pressures may occur at the trailing end, 120-deg. bearings are best studied as if they were Class A, eccentrically-loaded bearings, or Class D, offset bearings with $\beta < 120$ deg. In both cases, leading angle $\alpha$ should be taken as 60 deg., allowing the trailing angle $(\beta - \alpha)$ to be determined by the data in the class used. See Example 7.

Example 7.—Determine whether negative pressure would exist in a journal of diameter $2a = 6$ in., and width $b = 10$ in., carrying a total load $R = 600$ lb. at $N = 1000$ r.p.m., taking $\alpha/\beta$ ratios as follows: [1]. $\alpha/\beta = 0.44$; [2]. $\alpha/\beta = 0.52$; [3]. $\alpha/\beta = 0.62$. Clearance ratio $\eta/a = 0.002$, and the oil viscosity $\mu = 4.0 \times 10^{-6}$ Reyn.

*Solution.*—Determine correction factor $L_1$ corresponding to $l/b = (6\pi/10) \times (120/360) = 0.628$. From Fig. 38, $L_1 = 0.613$, and $w = 600/(6 \times 10 \times 0.613) = 16.30$. Since $\mu = 4.0 \times 10^{-6}$, the group

$$(w/\mu N)(\eta/a)^2 = [16.3/\{(4 \times 10^{-6}) \times 1000\}] \times 0.002^2 = 0.0163.$$

If an ordinate be erected at 0.0163 on the scale $(w/\mu N)(\eta/a)^2$ in Fig. 57 it will intersect the curves for $\alpha/\beta = 0.44$, 0.52, and 0.62 at the points [1], [2], and [3] respectively. Hence, with ratios of $\alpha/\beta$ of 0.44 and 0.62 negative pressure is quite likely to exist at the trailing and leading ends, respectively, of the bearing. With a ratio of $\alpha/\beta = 0.52$ the bearing probably will not have negative pressure.

Other items that may be determined from Fig. 57 are the total lift of the bearing and the point of maximum pressure in the oil film. See Example 8.

Example 8.—Determine the lift of the journal when in running position, and the point of maximum pressure in the oil film of a centrally-loaded, type Class C, 120-deg. clearance turbine bearing without a cap, with ratio of $\alpha/\beta = 0.56$; journal diameter $2a = 15$ in.; length $b = 30$ in.; vertical load $R = 67{,}500$ lb.; speed $N = 1500$ r.p.m. Clearance ratio $\eta/a = 0.001$ in. The oil at operating temperature has a viscosity $\mu = 3.4 \times 10^{-6}$ Reyn.

*Solution.*—Ratio $l/b = (15\,\pi/30) \times (120/360) = 0.524$, whence from Fig. 38, $L_1 = 0.673$.

$$w = R/(2a \times b \times L_1) = 67{,}500/(15 \times 30 \times 0.673) = 223.$$

$$(w/\mu N)(\eta/a)^2 = \{223/(3.4 \times 10^{-6} \times 1500)\} \times (0.001)^2 = 0.0437,$$

with which value Fig. 56 is entered. The ordinate erected at $(w/\mu N)(\eta/a)^2 = 0.0437$ intersects the curve $\alpha/\beta = 0.56$ at $\phi_H = 107$ deg., which corresponds to a value of $c = 0.3$.

$$\text{Lift} = \eta(1 - c \cos \phi_H) = 0.075\,[1 - \{0.3 \times (-0.29237)\}] = 0.0684 \text{ in.}$$

The point of maximum pressure $p_m$ is the value of $\theta_1$ at the point where the ordinate $(w/\mu N)(\eta/a)^2 = 0.0437$ intersects the curve $\alpha/\beta = 0.60$, which is $\theta_1 = 83$ deg. $p_m$, therefore, will be on the radius of the journal in running position, 83 deg. in the direction of rotation from the line $O-O'$ joining the center of the journal and the center of curvature of the bearing.

**SPEED LIMITATIONS OF OIL FILM BEARINGS.**—The upper limit of applicability of oil films in thrust and journal bearings has not yet been attained (1937). Tests conducted in 1934 on two opposed double thrust bearings measuring 6 1/4 in. diam. over the shoes, and two journal bearings, 2 1/2 in. diam. by 30 in. long, in the same mountings, showed that the bearings operated perfectly up to 12,000 r.p.m. The thrust capacities reached 2000 lb. per sq. in. before breakdown. Maximum peripheral speed of the thrust bearing was 330 ft. per sec.

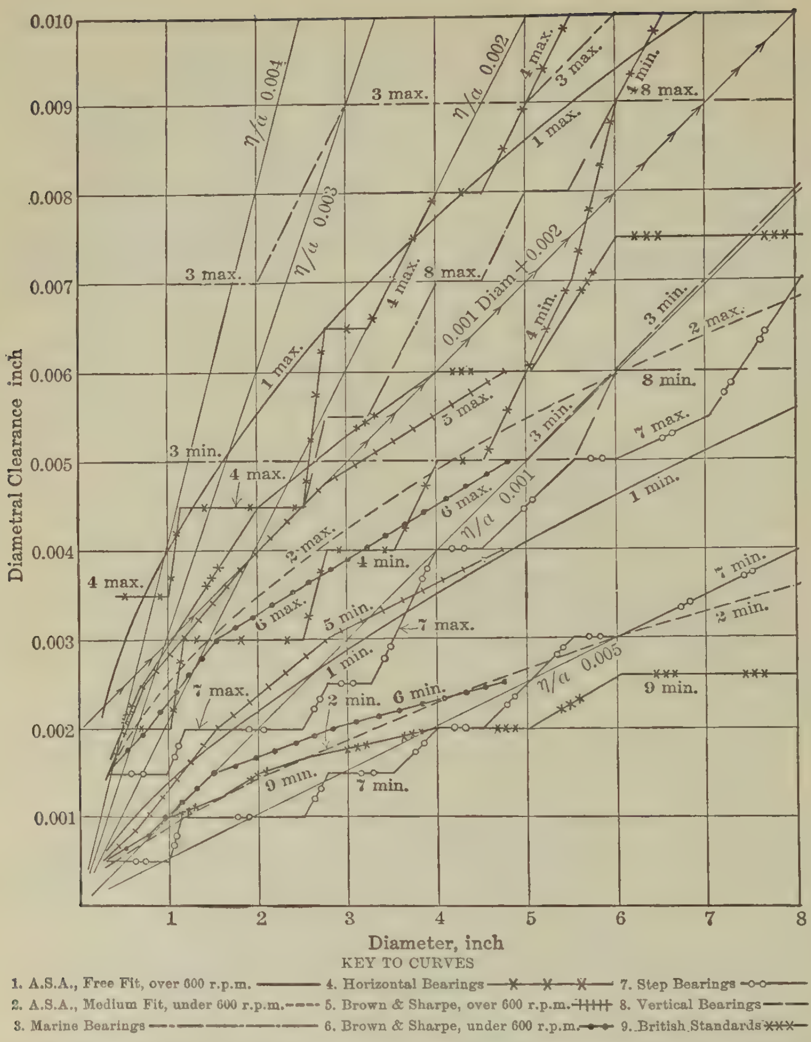

Fig. 59. Current Practice (1937) in Bearing Clearance, Shaft Diameter, 0 to 8 in. See Fig. 60 for Shafts 6 to 24 in. Diameter.

**BEARING PRESSURES AND SPEEDS.**—Fig. 58 gives the relation of (pressure × velocity), together with other data that are useful for analytical studies, on bearings covering a wide range of services. For journal bearings, the nominal unit pressure $p_o$ has been determined by the equation $p_o = R/2\,a\,b$, where $R$ = total load on bearing, lb.; $a$ = radius of bearing, in.; $b$ = width of bearing, in. Logarithmic scales are used for $p_o$ and $V$ so that straight lines will represent simple exponential relations. The diagonal lines sloping downward to the right give values of the product of $p_o\,V$ for any point on the chart. The heavy lines indicate, in general, the range of the data.

The diagonal lines slanting downward to the left, "Lines of Direction" and lines that may be drawn parallel to them, are used to study journal bearings. They afford means of obtaining the optimum relation between viscosity, journal diameter and clearance. For example, the dotted line from point $K$, extending across the scales of Kingsbury's optima for Classes A, B and C, leads to numerical values therein for equating with the symbol groups $(\mu/a) \times (a/\eta)^2$ and $(\mu/a)\,(a/h_o)^2$, where $\mu$ = coefficient of viscosity, Reyns; $a$ = radius of journal, in.; $\eta$ = radial clearance, in.; $h_0$ = minimum film thickness, in. The scale values of the symbol group are given for $l/b$ ratios from 0.8 to 1.5 for optimum journal bearings for minimum friction coefficient, based on a bearing arc $\beta = 120$ deg. Side leakage influence is allowed for the (length/width) ratios marked on the scales, based on Fig. 38.

**BEARING CLEARANCES.**—A study of bearing clearances indicates wide divergences in practice. Fig. 59 gives clearance data for marine bearings, horizontal bearings, vertical bearings, step bearings, Brown & Sharpe practice for over and under 600 r.p.m., respectively, the American Standards Association standards and British standards, up to a total clearance of 0.010 in. and diameters up to 8 in. Fig. 60 extends this range to larger clearances and diameters. The line marked 0.001 diam. + 0.002 shows a rule used by Kingsbury for standard duty journal bearings. In order that the other data may be interpreted with reference to the clearance ratio $\eta/a$, reference values of it are given from 0.0005 to 0.004. If clearances are chosen from these curves, they must for best results, be supplemented by a suitable oil.

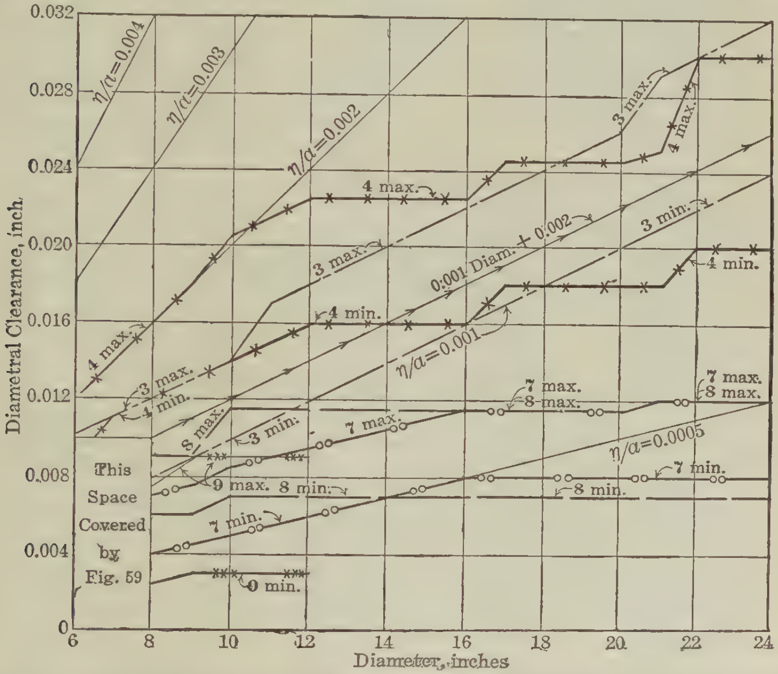

FIG. 60. Current Practice (1937) in Bearing Clearance, Shaft Diameter, 6 to 24 in. See Fig. 59 for Shaft Diameters 0 to 8 in., and key to curves.

## 5. THRUST BEARINGS

**THE THRUST PROBLEM.**—More or less axial load is encountered with every vertical shaft. With horizontal shafts, which are the most common, there usually is no real thrust load and only shaft shoulders are needed to hold the machine parts in proper axial relation.

**Heavy Horizontal Loads** are encountered in unbalanced centrifugal pumps and steam turbines, in marine propeller shafts, in industrial machines, and in some machine tools. When thrust loads are encountered at very low speed, the wear and the power lost in friction often are ignored and very inefficient bearings are used, although it is better practice to use rolling contact bearings in such service. With relatively high speeds and large shafts, as for marine propellers, the power loss is important, and efficient durable thrust bearings are used. For very high speeds with heavy thrust loads, as in steam turbines, the thrust bearing also must be efficient and durable.

**Light Horizontal Loads.**—Horizontal shafts, with little or no thrust load, often require close control of endwise position. This may be done by a collar on the shaft end as in Fig. 61. One collar in one bearing mounting then controls end-play. Using the shaft shoulder, as in Fig. 20, requires two bearing mountings. See Thrust Bearing Design and Construction below.

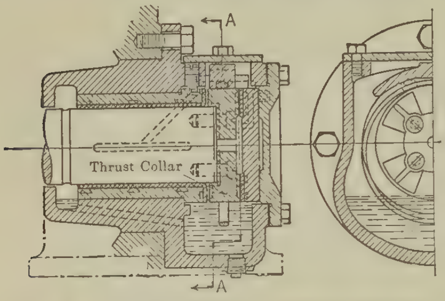

Fig. 61. Ring-oiled Journal and Thrust Bearing

**Vertical Loads.**—A vertical shaft in a machine always has a thrust load, due to the weight of the machine elements that in a horizontal shaft would be carried by journal bearings. However, a vertical shaft has no side loads on its journals except those produced by the operation of the machine itself. The thrust load on a vertical shaft either may be increased or reduced by loads produced by operation of the machine. Thus, in a hydroelectric generating unit, or a vertical centrifugal pump, hydraulic thrust in the runner increases the thrust load due to the weight of the revolving parts. The importance of the thrust problem depends on the combination of load and speed.

**THRUST BEARING DESIGN.**—Thrust bearings may be divided into two main groups, *viz.*, imperfectly lubricated and perfectly lubricated. The degrees of imperfection or perfection will vary. Among bearings that are perfectly lubricated, a bearing of one design may run with several times more friction than another, under otherwise identical conditions, and with no metallic contact of bearing faces during operation. Similarly, with imperfect lubrication, some bearings will run with higher friction than others, with the same oil, load and speed conditions, but with more or less metallic contact of the bearing faces always present.

**IMPERFECTLY LUBRICATED THRUST BEARINGS.**—Imperfect lubrication implies lack of provision for the functioning of adequate wedge-shaped films rather than lack of lubricant. See Perfect Lubrication, p. 13–44. For very low speed, heavy oils and hardness of bearing materials have been relied on to keep the rate of wear within reasonable limits. Such bearings should be placed in oil baths, if possible, so that lubricant may be continuously available. Grooving may be designed to keep oil from wasting, or to produce circulation that will continually change the oil on the bearing faces.

**Vertical Shafts.**—For this service the plain pivot, the multiple-disc-supported pivot, the plain ring thrust, the washer-supported ring thrust, Figs. 62 to 65, are used. The grooves in these bearings, if submerged in oil, should be carefully formed, usually in the upward faces, and with rounded edges, as in Fig. 66, in the harder surface. If oil is present in only minute quantities, grooves should be in the downward face. Further improvement

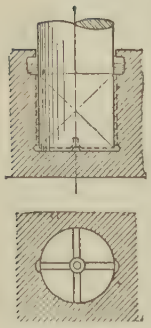

Fig. 62. Plain Pivot Thrust Bearing

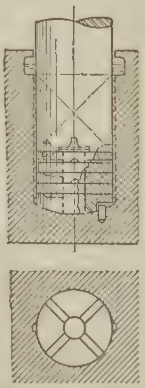

Fig. 63. Multiple-disc-supported Pivot Thrust Bearing

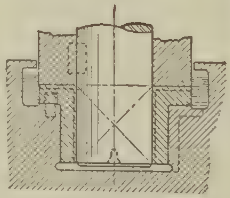

Fig. 64. Plain Ring Thrust Bearing

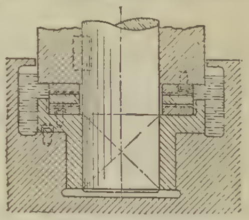

Fig. 65. Washer-supported Ring Thrust Bearing

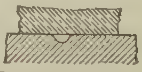

Fig. 66. Form of Oil Groove

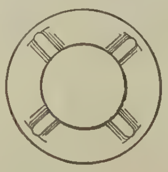

Fig. 67. Arrangement of Groove in Thrust Washer

can be made by slightly tapering the grooved bearing face for a distance at least equal to the width of the oil groove, on each side of the groove, but using not more than half the total surface for grooves and tapers. Two to four oil grooves usually are enough. For large diameters, or areas where radial width is small compared with the circumference, more grooves may be used. The size of the groove will vary, increasing with size of the bearing, sluggishness of the lubricant, and speed of rotation. If an oil bath cannot be used, it is best to stop the grooves short of the circumference of the disc or washer, and feed oil to the grooves from the center outward. See Fig. 67.

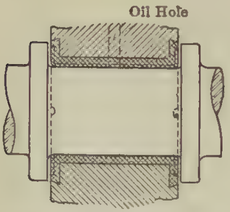

Fig. 68. Bearing to Take Light Thrust in Two Directions

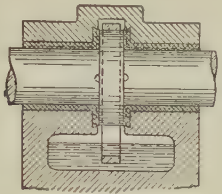

Fig. 69. Ring-oiled Two-direction Bearing for Light Thrust Load

**Horizontal Shafts.**—Conditions usually are quite different from those of vertical shafts. An oil bath is less easily provided. Also, because of end-play, it is difficult to prevent oil leaking away from the thrust surface, especially when thrust action is intermittent. For a simple construction like Fig. 68, thrust face grooves may be most easily cut in the stationary bearing face, although the harder face is preferable. Grooves should stop short of the outer diameter of the thrust collar. Sometimes a thrust collar, integral with or fastened to the shaft, is placed between two short journal bearings whose adjacent sides are enlarged to present reasonable thrust surfaces to the collar. If of sufficient diameter, this collar may be used to lubricate all bearing surfaces from a well below the shaft. Otherwise a ring may be used as in Fig. 69.

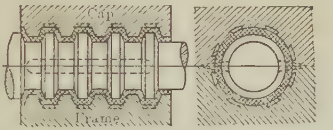

Fig. 70. Multiple-collar Bearing Sometimes Used in Woodworking Machinery to Position Spindle

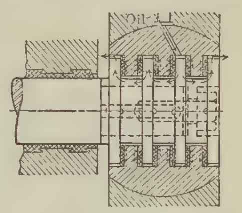

Fig. 71. Multi-collar Thrust Bearing for Light Loads

For data on friction coefficients of imperfectly lubricated thrust bearings, see p. 8–24. In such bearings the coefficient will, if bearing is adequately oiled, vary from 0.20 downward to about 0.02. This lower value would be considered very high for a perfectly lubricated bearing surface. See p. 8–28 for friction coefficients possible with perfect lubrication.

**Multi-collar Thrust Bearings** are used in several forms, more or less well made. In woodworking machinery, a bearing-metal lining is poured into the frame and cap, around a grooved shaft (Fig. 70). Oil is best applied at the sides. Such a bearing if lightly loaded, and not too tightly clamped on the shaft, may serve as a combined journal and thrust bearing, but it is not considered good practice. Sometimes the cap of such a bearing is made axially adjustable for control of end-play. Fig. 71 shows a multi-collar bearing used only to carry light thrust loads. It is adjacent to an adequate journal bearing. Oil under pressure may be applied as marked, and caused to flow through suitable grooves back and forth across the faces of the collars. If carefully made, and when oil grooves are properly designed with adjacent surfaces properly beveled, these bearings can carry moderate loads even at high speed.

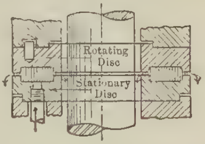

Fig. 72. Oil Pressure Thrust Bearing

One serious difficulty with all multi-collar thrust bearings is the inequality of distribution of load among the collars. To help overcome this in large bearings for marine service, crescent shaped elements, called horseshoes, with soft metal faces, are placed between the shaft collars. Sometimes grease is used for lubrication, but usually oil is supplied from a bath below the shaft into which the collars dip. The shoes sometimes are water-cooled by passages, but, for high-speed bearings, a water coil usually is placed in the bath below the collars. Horseshoes in marine practice are loaded to from 30 to 70 lb. per sq. in. They now are seldom used, because more efficient and more durable types of bearings are available, that operate with about one tenth the power loss. See pp. 13–36 to 13–39.

**THE OIL PRESSURE THRUST BEARING** employs two discs constructed as in Fig. 72. Oil is pumped under high pressure into the stationary disc at a definite rate, lifting the upper or rotating disc until oil discharge rate equals supply rate. Accumulators are required to protect against stoppage of the pumps. Rollers sometimes are provided to prevent contact of narrow faces of discs when oil supply fails. If the discs are permitted to rub they will "flash" and be damaged. Friction in the bearing itself is very low, but considerable power is required to drive the pumps. These bearings, therefore, are uneconomical, and are little used to-day.

**PERFECTLY LUBRICATED THRUST BEARINGS.**—See Perfect Lubrication, p. 13–44, for a discussion of the principles underlying the formation of the tapered oil film. Such films, in various forms, exist between the bearing faces of the thrust bearings described below.

**The Fixed Wedge Film** type of thrust bearing was suggested in 1888 by Prof. Archibald Barr, when discussing Beauchamp Tower's then recent tests on plain collar thrust bearings. It is obvious that part of the thrust bearing face must be flat to permit the collar to start and stop under load without undue concentration of pressure. The wedge-shape film in a bearing of this kind is unable to lift its load until a fair speed is attained. Conversely, it is apt to stop suddenly when slowing down. The fixed wedge may be combined with a flat surface in two ways: 1. Alternate bevels and flats with grooves *G* between, Fig. 73; 2. A supply groove *G* at the thick end of the bevel, omitting the groove between the bevel and the flat in the direction of motion, Fig. 74. This construction is used in the Gibbs thrust bearing, built by S. Morgan Smith Co., York, Pa., for both horizontal and vertical shafts. Bearing pressures range from 200 to 300 lb. per sq. in.

Fig. 78. Restrained Wedge-film Bearing

A characteristic of these bearings is that the slope of the wedge remains constant for all conditions of load, speed, oil viscosity, and temperature for a given bearing. The film thickness, however, will vary automatically as these conditions change, provided the speed is great enough to separate the flat faces.

**The Free Wedge Film** (Fig. 75) type of thrust bearing (Kingsbury Thrust Bearing) was conceived, constructed and tested in 1896 by Prof. Albert Kingsbury. It is built by the Kingsbury Machine Works, Inc., Philadelphia. A parallel, but independent, development of the similar Michell thrust bearing has taken place in England. The bearing members (shoes) in this type are tiltably mounted, and are free to form automatically the most efficient natural oil film required by each different combination of load, speed, viscosity and temperature to which the bearing is subjected.

**The Restrained Wedge Film** type of thrust bearing appears in several forms. In this type the elements forming the films are not fully free, but do respond, in a limited degree, to change of load, speed, viscosity and temperature. One of these, Fig. 76, invented by H. G. Reist about 1915, is built by the General Electric Co. Its stationary element is a babbitted, relatively thin, steel ring, with one radial gap, mounted on many small stiff precompressed springs. Radial grooves are cut in both of the opposing bearing faces to supply cool oil to the bearing faces. Wedge film formation is restrained by the stiffness inherent in the flexible babbitted plate, which is finished flat. During operation, a film of oil thick enough to prevent metallic contact is maintained between the rotating and stationary plates. The film is not sensitive to changes of speed or loading, nor will it be disrupted by a small amount of sludge or small particles. Both stationary and rotating grooves are chamfered to direct the oil between the surfaces, and the film forms when half the distance between grooves has been traversed. The flexibility of the structure insures the formation of a film of the most effective shape. In the event of misalignment, the flexible support automatically deflects to equalize the pressure distribution over the entire bearing. The operation of the bearing depends on the combined effects of the grooved rotating and stationary plates and of the flexible support.

Fig. 77 shows a second form of restrained-wedge-film bearing, inventor unknown. Restraint of wedge film formation is imposed by the rigid neck and the stiff portions of the adjacent shoe body. This is an integral structure. The bearing faces of the shoe bodies are finished flat. The flexing of the overhung portion takes place under the pressures incident to the formation of the film.

A third and rather unusual restrained wedge film, invented by Elmer D. Sperry, is shown in Fig. 78. The supporting base is faced with bearing metal of thickness that varies considerably. Babbitt metal has a coefficient of elasticity much greater than iron or steel. Hence if the thickness is greater where the pressures are lower a wedge shaped film may be formed, though considerably restrained.

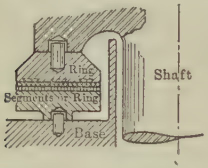

Fig. 79. Radial Section of Thrust Bearing Indicating Radial Tilting

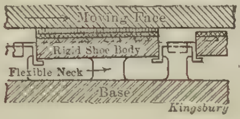

Fig. 80. Thrust Bearing Shoe on Flexible Neck

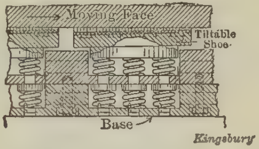

Fig. 81. Thrust Bearing with Duplex Spring-supported Shoes

Radial tiltability may be given to relatively thick bearing rings by applying the load to their backs through annular supporting ribs. See Fig. 79. Also the lower ring may be made in separate segments that have freedom only for radial tilting, in which case the ribs supporting the segments may be tangential. Such elements may have fixed bevel bearing faces or flexible leading portions, as already described.

**The Semi-free Wedge Film** is formed when the tilting shoe is mounted on a flexible neck, Fig. 80. A fairly efficient form of thrust bearing of simple integral structure results. A certain amount of freedom must be sacrificed to preserve the requisite ruggedness.

Another form in which this semi-free film appears is that in which separate shoes are mounted on springs or other elastic means. See Fig. 81. This particular design contains other features important for resiliently supported bearings, *i.e.*, means for preventing and for damping vibration, without interference with the normal functioning of the bearing under variable load.

**Film Forms.**—When the relative motion is circular, instead of straight-line, the flat faced wedge film is not geometrically a flat wedge in the developed section of the path of relative motion, but is a sine curve wedge, as in journal bearings. There also are changes in film shape due to elasticity of materials, and to temperature variations. Thrust bearing films, therefore, usually are of a composite nature. Occasionally a composite form is purposely given the film, as when beveling is added to the leading or trailing portions of the bearing face of the freely tilting shoe. A variable composite film appears in the Reist bearing, Fig. 76, in which both bearing faces are provided with oil grooves. The double grooving tends alternately to build up and to break down the pressure in the films, but it helps the radial flow of oil across the bearing faces.

**CONSTRUCTION DETAILS.—Reversible Bearings.**—In general a thrust bearing may be made suitable for both directions of rotation, *i.e.*, reversible, by making its supporting feature symmetrical with respect to the bearing face segments or grooves. For example, the free-wedge type may have its shoes supported in the middle, and it loses little efficiency thereby. The fixed-wedge type requires the provision of an additional beveled portion, tapered in the opposite direction. When the limit of dead load supportable by the flat parallel portion of the bearing face is reached, the reversible fixed-wedge bearing area would have to be larger than if made for one direction only.

**Aligning and Equalizing Means for Thrust Bearings.**—When the machine is so accurately made that alignment of shafting is perfect within the limits of the film thicknesses in the bearings and the elasticity of the component parts, no aligning means need be provided. This also is true when the bearings are so placed with respect to the machine frame that the slight elasticity of the frame itself enables the bearings to preserve their proper alignment. However, it often is desirable to provide some aligning means within the thrust bearing, and the methods cited below are employed.

The design of aligning means should be governed by the misalignment to be corrected, as initial, subsequent, or continuous or rapidly recurring. The durability of the aligning means, therefore, is an important consideration in the selection of a thrust bearing. Special forms have been devised for such service as gyro-stabilizers and for thrust collars that are out of square with the shaft.

1. **The Spherical Washer,** Fig. 83, is the commonest form and has several advantages, one of which is ruggedness. When used with three freely tilting shoes it tends to equalize the load distribution among them. For best efficiency, the mean angle of the spherical faces should be about 45 deg. Even so, when once well loaded, an eccentricity of the load equal to more than half the projected radius to the mean zone of the spherical fit, is required before slipping will take place. Hence, this method of equalizing or aligning is not sensitively responsive to variations in alignment under load.

2. **Adjustable Bearings.**—When freely tilting shoes are mounted on jack screws, the latter may be used for initial setting of height, alignment and equalization of load, but are not useful for preserving alignment when the supporting structure shifts.

3. **Elastic Support** is an approximate aligning means, and also an approximate equalizing means for various portions of a bearing when little correction need be made. With the stiff springs necessarily employed, carefully preliminary setting of the thrust deck is essential. Means to prevent or control vibration must be employed. See discussion of Figs. 76 and 81.

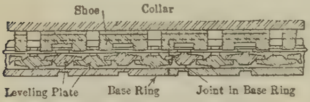

FIG. 82. Equalizing Supports of Kingsbury Thrust Bearing

4. **Equalizing Supports.**—Systems of rocking levers are used effectively in Kingsbury bearings for alignment and equalization. They continue effective, even in the presence of considerable subsequent displacement of the thrust deck. Their range and accuracy are considerable. See Fig. 82. This form has been adapted, with roller contacts, to very large hydroelectric bearings.

**DATA ON STANDARD KINGSBURY THRUST BEARINGS.**—Because of the relatively recent development of these oil film bearings their standardization is not as widely known as that of ball and roller bearings. It has, therefore, been thought desirable to place herein the principal dimensions of one important generally useful line of Kingsbury bearings and to illustrate a number of types of mountings in which they are used.

**Internal Parts.**—The self-aligning equalizing types of Kingsbury thrust bearings consist mainly of the shoes and their supporting structures shown in Figs. 83 and 84. The overall dimensions of these 3-shoe and 6-shoe elements are made the same for interchangeability. See Table 10. These elements may be used either horizontally or vertically, but usually they rely on a ring or on a surrounding wall of the mounting to hold the shoes radially in place.

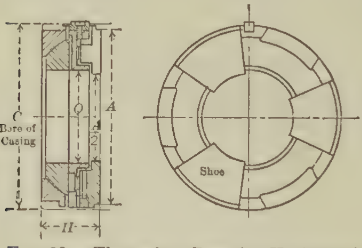

FIG. 83. Three-shoe Base for Horizontal or Vertical Thrust Bearing

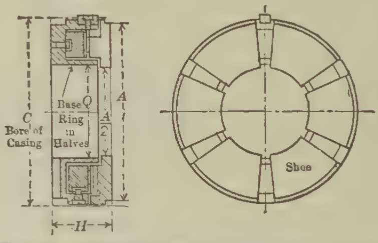

FIG. 84. Six-shoe Base for Horizontal or Vertical Thrust Bearing

Commonly-used combinations of these elements are: 1. Horizontal 3-shoe base and 6-shoe base with thrust collar between, a combination useful for thrust loads that are heavier in one direction than the other; 2. Single horizontal bearing for one-way thrust with 6-shoe base and separate collar; 3. Horizontal double 6-shoe bearing for two-way thrust with separate collar (see Fig. 85); 4. Horizontal double 6-shoe bearing with collar integral with shaft (See Fig. 86). In this construction the 6-shoe bases are made in halves; 5. Horizontal double two-way bearings with bases in halves, with one 2-shoe tilting ring type base, and one 6-shoe base, the major thrust being taken by the 6-shoe bearing; 6. Vertical 3-shoe thrust bearing, spherically seated base (See Fig. 83), and runner; 7. Vertical 6-shoe vertical bearing and runner; 8. Vertical 3-shoe spherically seated bearing with spherically seated shoe-retaining base, and runner (See Fig. 87); 9. Vertical 6-shoe thrust bearing with shoe retaining base and runner (see Fig. 88); 10. Vertical 6-shoe thrust bearing with runner and shoe-retaining straps.

**THRUST BEARING CAPACITIES.**—Table 10 is based on the practice of Kingsbury Machine Works for average conditions in bearings with freely tilting shoes of proportions shown in Table 11. For similar information on other bearing types, consult the manufacturers concerned. Capacity depends on mechanical strength, materials used, surface speed, oil viscosity, and temperature. It may be increased with speed until a limit is reached, imposed by other considerations, such as starting and stopping conditions. It is assumed that safety while running depends on the maintenance of the oil film above some minimum thickness that experience has proved to be adequate. Any capacity table must, therefore, have its limitations stated, because bearings can be designed and operated under vastly greater loads than indicated in Table 10, which applies to thrust bearings as usually applied to steam turbines, centrifugal pumps, ordinary industrial machinery, marine propulsion, and hydroelectric units.

Load Correction Factors

| $l/b$ = | 0.50 | 0.67 | 1.00 | 1.33 | 1.50 | 2.00 |
|---|---|---|---|---|---|---|
| Correction Factor = | 1.557 | 1.357 | 1.000 | 0.732 | 0.630 | 0.423 |

film thickness is a criterion of bearing safety. Table 11, based on the experience of Kingsbury is a basic loading table that shows minimum film thicknesses to be expected under given conditions for average thrust bearings of steam turbines, centrifugal pumps, ordinary industrial machinery, hydro-electric units, and marine propulsion, where the oil is not too heavy. Values in the table are based on a mean viscosity coefficient, within the film at operating temperature, of $3.4 \times 10^{-6}$ Reyn = 0.23 poise, equivalent to 125 sec. Saybolt Universal viscosity with oil of 0.875 specific gravity. Film thickness is taken on the median line of the trailing edge of the shoe. Load correction factors are based on a study of side leakage. See p. 13–16.

**FRICTION IN THRUST BEARINGS.**—See *Mech. Engg.*, April 1927, p. 375. The friction coefficient for a perfectly lubricated surface moving in a straight line on tiltable rectangular shoes (approximately the condition in Kingsbury and Michell bearings) is given by

$$\lambda = Fb/R = 1.81\,k\sqrt{\mu v / l p_0} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [13]$$

where $k$ is a factor given by Fig. 89 based on Michell's data (9). Other notation is as given on p. 13–15.

**POWER LOSSES IN THRUST BEARINGS.**—Table 12 gives the relations of speed, capacity and friction of Kingsbury thrust bearings when the mean viscosity of oil in the films is $3.4 \times 10^{-6}$ Reyn, the ratio of $l/b$ of the shoes is 4/3, and the outer diameter $D$, in., of the bearing is $4\,d/3$, where $d$ = mean diameter. For a 6-shoe bearing the net area of segments is $^1/_2 D^2$. Friction coefficients and power losses are based on a value of side leakage correction factor of $k$ = 1.6. Corrections can be made for other conditions by application of formula [13]. For similar data on thrust bearings of other types, the several bearing manufacturers should be consulted.

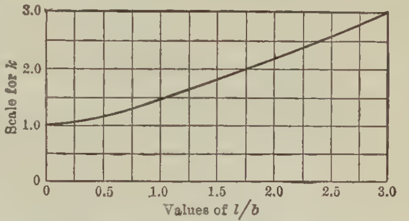

Fig. 89. Friction Coefficient Factor $k$, Interpreted from Michell's Analysis of Flat Bearing Surfaces

**THRUST BEARING MOUNTINGS.**—The following paragraphs describe typical methods of mounting thrust bearings.

**Combined Vertical Thrust and Guide Bearings.**—The combined flat thrust and cylindrical guide bearing, Fig. 90, usually has three or six thrust shoes $T$, the thrust runner $R$ being submerged. Oil, lifted by centrifugal action, fills the space around the pivoted guide bearing shoe $G$ and at the

* Multiply the power losses in third column by these factors to correct for speed and load.

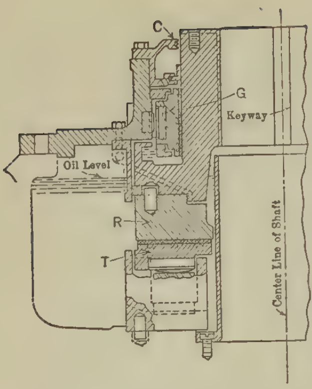

FIG. 90. Combined Vertical Guide and Thrust Bearing

top flows back to the oil bath. The upper special seal ring *C* prevents aeration. Load on thrust shoes is equalized as in the bearing Fig. 82. A cooling coil is used if required.

The self-aligning submerged guide bearing Fig. 91, has guide shoes similar to those in Fig. 90, but the mounting and oil well are so designed as to submerge the shoes. The arrangement shown is suitable for moderate speeds. For high speeds, the bearing is arranged to circulate oil from the bottom of the oil well and to keep the shoe cavity under moderate oil pressure to prevent foaming. In an alternative arrangement, Fig. 92, the guide shoes *G* bear directly against the shaft. Oil is lifted to the bearing by a centrifugal or viscosity pumping device on the shaft. The shoes dip in oil retained in the basin of the pumping device and thereby have capillary oiling for starting.

**SPHERICAL THRUST BEARING,** Fig. 93, performs in one unit the functions of both the flat thrust and the guide bearing, Fig. 90. Six pivoted shoes *T* are seated in the solid base ring *B*, the shoe faces being concave against the spherical-faced runner *R*. The bearing will sustain a radial load of about 15% of the downward load, and unlike a cylindrical guide bearing, it requires no radial running clearance. The shaft, therefore, will run accurately centered. For high speeds, an air seal ring *C* around the runner minimizes foaming. A narrow bronze bushing *S*, surrounding, and loose on, the thrust block hub *H* holds the parts together in handling. For temporary radial overloads, or lifting of the shaft, an auxiliary guide bearing may be applied above the spherical thrust bearing, using the same guide parts as in Fig. 90. The guide bearing shoes then are bored with a larger running clearance, and act only if the shaft lifts. Four 30-in. bearings of this type, operating at 500 r.p.m. are used in condensers at the Leaside Station, Toronto, Ont.

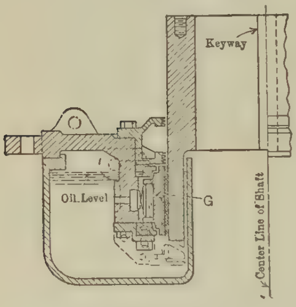

FIG. 91. Self-aligning Submerged Type Combination Guide and Thrust Bearing

**MARINE TYPE AUTOMATICALLY LUBRICATED THRUST MOUNTING,** Fig. 94, is commonly used with Kingsbury thrust bearings abaft ship propulsion machinery, where the shaft diameter is large and the full area of the thrust collar is not required to carry the load. Two thrust shoes in each end of the mounting are adjusted by jack screws and hardened thrust pins. The adjacent journal bearing has a removable split shell. End closures commonly are of non-wearing types. See Figs. 21 and 22. Oil lifted by the thrust collar is directed to the bearing surfaces.

The disc-oiled propeller shaft bearing Fig. 95 has a short self-aligning bearing shell and an oiling disc *D* operating on the viscosity pumping principle. The disc delivers oil to a hopper *H* in the cap of the bearing shell. A crown ring closure (Fig. 22) prevents leakage at the housing opening.

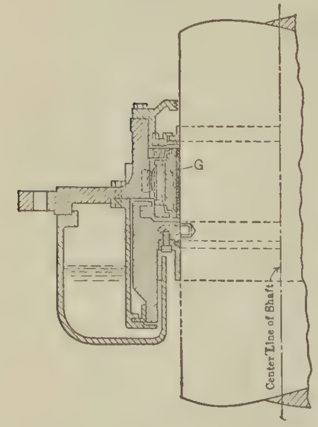

FIG. 92. Self-aligning Guide and Thrust Bearing with Shoes Bearing on Shaft

**HORIZONTAL MOUNTINGS FOR HIGH-SPEED COMBINED THRUST AND JOURNAL BEARINGS,** Fig. 96, are used in large high-speed centrifugal pumps. The double thrust elements have two, three or six shoes, depending on the load. Oil circulation is maintained by a viscosity pump 5 on the periphery of the thrust collar, and is automatically reversible with change in direction of rotation. With rotation in the direction of the arrow, oil is drawn from reservoir at *C*, flows through passages *B* toward the shaft, and thence outward between the shoes. It passes to the cooler through space *D* and passage *E*. Holes *A* are used for rotation in opposite direction. Passage *G* delivers oil to the journal. The

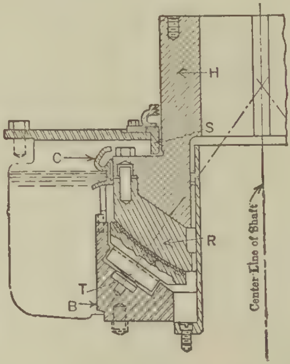

FIG. 93. Spherical Thrust Bearing

mounting may be capped at *L* for an oil supply to a separate journal bearing, with return at end.

**THRUST BEARINGS FOR HYDROELECTRIC UNITS.**—The field in which the largest thrust bearings are required is that of hydroelectric units of the vertical type. The turbines for large hydroelectric units usually are made by one manufacturer and the generators by another. Thrust bearings usually are supplied with the generators. Examples of practice in thrust bearing application follow.

**Boulder Dam.**—Two General Electric generators, operating at 180 r.p.m., are carried on Kingsbury equalizing thrust bearings 85 1/2 in. diameter. The thrust load is 1,800,000 lb. Two other General Electric generators, also operating at 180 r.p.m., are carried on General Electric thrust bearings (Fig. 76). The thrust load is 1,786,000 lb. An Allis-Chalmers generator operating at 257 r.p.m., with a thrust load of 680,000 lb. is carried on a Kingsbury adjustable-type thrust bearing 57 in. diam. Two Westinghouse generators are carried on 84-in. Kingsbury guide-thrust bearings with eight babbitt-lined shoes, each supported by separate adjusting screws which permit alignment and equalization of load. The thrust load is 1,700,000 lb.

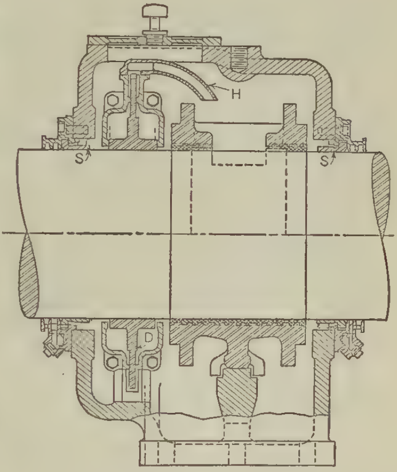

FIG. 95. Disc-oiled Propeller Shaft Bearing

**McIndoes Plant,** New England Power Construction Co., has four Gibbs bearings, on vertical hydroelectric generators of 3500 and 5120 Hp., respectively, operating at 150 r.p.m. The load is 220,000 lb. The Bellows Falls, Vt., plant of the same company has three 17,500-Hp. vertical hydroelectric generators operating at 85.7 r.p.m. They are fitted with Gibbs bearings taking a thrust load of 520,000 lb.

**Pickwick Landing (T.V.A.).**—The 46,000-kva. umbrella-type Westinghouse generators are carried on Kingsbury thrust bearings 105 in. diam., designed to support a total thrust load of 2,500,000 lb., or a unit pressure of 405 lb. per sq. in., with a guide bearing adjacent to the thrust bearing. Each thrust bearing has 10 screw-adjusted shoes, supported in a 10-arm bracket. The rigid bearing produces a restraining effect on the rotor, insuring satisfactory operation, even if the upper guide bearing is removed.

**Bonneville Dam.**—Two 48,000-kva. General Electric generators operating at 75 r.p.m. are carried on General Electric thrust bearings. The thrust load is 3,000,000 lb.

**Safe Harbor.**—Three General Electric generators operating at 109 r.p.m. are carried on Kingsbury adjustable thrust bearings 82 in. diam., adapted to the continuous girder type of support. The thrust load is 1,750,000 lb.

**Guntersville.**—Two General Electric generators, normal speed 69.2 r.p.m., are carried on Kingsbury thrust bearings 87 in. diam., of the same type as used at Safe Harbor. Thrust load is 2,000,000 lb.

**Rosetilla Station,** Chihuahua, Mexico, has a General Electric generator, operating at 120 r.p.m., with a 45-in. Kingsbury spherical thrust bearing, (Fig. 93) carrying a thrust load of 300,000 lb.

**Russian Hydroelectric Stations.**—Among the largest thrust bearings are the General Electric bearings used in nine 77,500-kva. generators in Russia, operating at 88 r.p.m. They carry thrust loads of 2,000,000 lb.

## 6. PERFECT LUBRICATION OF BEARINGS

**VISCOUS FLOW.**—Perfect lubrication is based on the principles of viscous flow, *i.e.*, each particle moves in a direction parallel to the boundary of the enclosing channel. The force that opposes viscous flow of a liquid is known as the resistance to distortion. Let $V_u$, $V_l$ = respectively, velocity of the upper and lower surfaces of a film, and $T$ = thickness. Then $(V_u - V_l)/T = U/T$ = rate of distortion of the film. Let $f$ = force acting on the upper surface of a film to produce a velocity $U$. Then the coefficient of viscosity $\mu$ is

$$\mu = f/(U/T); \quad f = \mu(U/T) \quad . \; . \; . \; . \; . \; . \; . \; . \; . \quad [14]$$

These are the fundamental formulas of the study of viscous flow. Equation [14] can be used to approximate the frictional resistance to rotation of a journal in a bearing when surface speed, film thickness and viscosity are known.

**Friction and Viscosity.**—The relation between friction and viscosity was first expressed by Petroff (1), who assumed that a shaft runs concentrically with its sleeve bearing. This assumption is valid for high-speed, moderately-loaded bearings whose journals run nearly concentrically in practically full-sleeve bearings. Let $a$ = radius of journal; $b$ = width of journal; $N$ = rev. per min.; other notation as before. (See p. 13-15.) Then the tangential friction $F$, resisting rotation at the surface of the journal, is $F = 2\,\pi\,a\,b\,f$, and the surface speed of the journal is $2\,\pi\,a\,N/60$. Combining these two expressions

$$F = \mu\,\pi^2\,a^2\,b\,N/15\,T \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \quad [15]^*$$

The friction force $F$ can be combined with speed and expressed as power loss.

Viscosity coefficient $\mu$ must be expressed in Reyns, $\mu_E$, if dimensions are in inches, and in poises $\mu_M$ or centipoises $Z$ if they are in the metric system. The following relations hold: $\mu_M/\mu_E = 69{,}000$; $\mu_E/\mu_M = 0.0000145$; $Z/\mu_M = 100$; $Z/\mu_E = 6{,}900{,}000$.

**Viscous Flow through Tubes.**†—If it be assumed that there is no molecular slippage of liquid at the tube surface, the laws of viscous flow may be applied to determine the volume and velocity of flow in tubes. Let $V_t$ = volume of flow; $t$ = time, seconds; $P_1$, $P_2$ = respectively, the pressure acting on the liquid at the entering and leaving ends of the tube; $h$ = diameter of tube or thickness of film; $L$ = length of tube; $u$ = linear velocity of flow, and $y$ = fraction of $h$ at which velocity $u$ is determined. Then

$$V_t/t = \{\pi\,(P_1 - P_2)\,h^4\}/128\,\mu\,L \quad . \; . \; . \; . \; . \; . \; . \; . \quad [16]$$

$$u = \{(P_1 - P_2)\,(h\,y - y^2)\}/4\,\mu\,L \quad . \; . \; . \; . \; . \; . \; . \quad [17]$$

**Viscous Flow between Parallel Plates,**† neglecting the influence of the sides, if the plates form a closed channel, is expressed by

$$V_p/t = \{b\,h^3\,(P_1 - P_2)\}/12\,\mu\,L \quad . \; . \; . \; . \; . \; . \; . \; . \quad [18]$$

$$u = \{(P_1 - P_2)\,(h\,y - y^2)/2\,\mu\,L \quad . \; . \; . \; . \; . \; . \; . \quad [19]$$

where $b$ = width of plates, other notation being as before. In equations [16] to [19] only one system of units can be employed (English or metric) and the viscosity coefficient $\mu$ must be in the same system.

**Viscous Flow from Approaching Plates.**—The time rate at which two parallel surfaces will approach when the space between is filled with a viscous liquid, under the conditions of elliptical plates with no central cavity, no oil supply, and the upper plate moving downward under a constant normal force $R$, was found by Osborne Reynolds (2) to be as follows:

$$t = \{(3\mu\,\pi\,a^3c^3)/2R(a^2 + c^2)\}\,\{(1/h_1^2) - (1/h_2^2)\} \quad . \; . \; . \; . \quad [20]$$

$$P_4 = 2R/\pi\,a\,c \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; . \quad [21]$$

$$P_5 = -(2R/\pi\,a\,c)\,\{(x^2/a^2) + (z^2/c^2) - 1\} \quad . \; . \; . \; . \; . \; . \; . \; . \quad [22]$$

where $a$, $c$ = respectively, semi-major and semi-minor axes of the ellipse; $x$, $z$ = co-ordinates of any point, measured respectively from $c$ and $a$; $R$ = total pressure on plate, lb.; $h_1$, $h_2$ = distance between plates at start and finish, respectively, of the interval considered; $P_4$ = pressure of oil at center of plate; $P_5$ = pressure of oil at any point with co-ordinates $x$ and $z$.

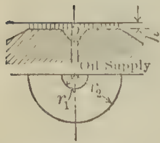

FIG. 97. Separation of Faces by Pressure Oil

**Separation of Circular Plates by High Pressure Oil.**—See Fig. 97. If oil be forced into the recess $D$ under sufficient pressure to cause outward radial flow, the plates will be separated. Two cases may be considered.

**Notation.**—$P_1$ = pressure of oil supply to recess $D$; $P_2$ = oil pressure at any radius $r$; $P_o$ = specific pressure on plate produced by load = $R/\pi\,r_2^2$; $h$ = distance plates are separated; $R$ = total load on plate, lb.; $r_1$, $r_2$ = respectively, radius of cavity and of plate; $G$ = oil supply, gal. per min.; $t$ = time, sec., for plates to move from height $h_2$ to height $h_1$; $\mu$ = viscosity, Reyns. Dimensions are inches; pressures in lb. per sq. in.

---

* Petroff's formula was more complicated because he assumed slippage of oil on the bearing surfaces.

† Influence of acceleration at entrance is not included.

Case 1. Circular Plate, load carried by continuous flow of oil under pressure:

$$G = 0.0867h^3R/\mu\,(r_2^2 - r_1^2) \qquad [23]$$

$$P_1 = 2R \log_e (r_2/r_1)/\pi\,(r_2^2 - r_1^2) = 7.35\,\mu G \log_e (r_2/r_1)/h^3 \qquad [24]$$

$$P = 2\,R \log_e (r_2/r)/\pi\,(r_2^2 - r_1^2) \qquad [25]$$

$$P_1/P_o = 2r_2^2 \log_e (r_2 - r_1)/(r_2^2 - r_1^2) \qquad [26]$$

Case 2. Circular Plates, oil supply stopped, plates moving together; oil flow radially outward:

$$t = \{3\mu\pi\,(r_2^4 - r_1^4)/4R\}\,\{(1/h_1^2) - (1/h_2^2) \qquad [27]$$

$$P_2 = 2R/\pi\,(r_2^2 - r_1^2) \qquad [28]$$

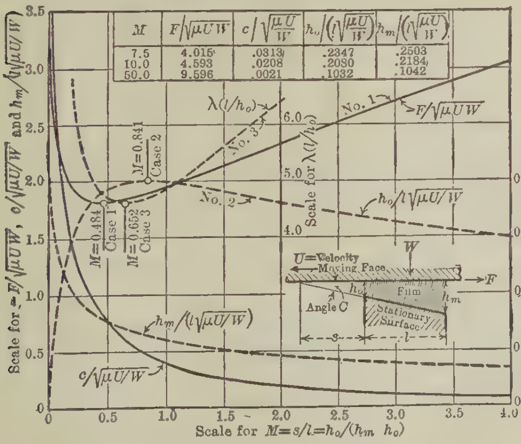
$$P = 2R\,(r_2^2 - r_1^2)/\pi\,(r_2^4 - r_1^4) \qquad [29]$$

**THE TAPERED OIL FILM.**—In 1883 Beauchamp Tower discovered the existence of an oil film completely separating a journal from its bearing. In 1896, Albert Kingsbury (4) discovered that the film was wedge shaped. The hydrodynamical theory, on which modern lubricating practice is based was developed from Tower's work by Osborne Reynolds (2). A good review of Reynolds analysis is given in Kingsbury's paper (4).

**Side Leakage.**—Reynolds neglected the influence of side leakage on pressure and friction in the oil film, and determined the maximum pressures that a bearing could develop with a given film, under ideal conditions. He, therefore, set an upper limit or standard of comparison for actual conditions. However, all other conditions being the same, the narrower a bearing surface, perpendicular to the direction of motion, the lower will be the pressures developed in a film of given form and thickness, due to a larger percentage of the oil drawn in at the front edge leaking from the sides of the narrower bearing. See p. 13–16.

**Film Thickness.**—The factor of safety of a bearing depends largely on film thickness and shape, and minimum thickness is an excellent criterion of bearing safety. Film thickness is difficult to measure. Hence it usually is calculated for reference purposes from data of bearings that have proved successful in service. See Table 11 for calculated capacities of minimum film thicknesses.

**Viscosity Change within Oil Film.**—The friction generated in a bearing whose surfaces are completely separated by an oil film, for the usual range of speeds, is mainly produced within the film itself. It depends on the viscosity of the film, the film thickness, and form, the speed, and the extent and shape of the bearing surfaces covered by the film. See Viscous Flow above. Some of the heat generated in the oil flowing through a bearing film, with consequent rise of temperature which reduces viscosity, passes into the bearing faces. The rest passes out with the oil discharged from the sides and at the far end of the film. The maximum possible rise of temperature in a perfect film may be simply calculated from the mean film thickness, the speed, and the specific heat of oil, assuming that all the heat is absorbed by the film, and that the flow through it is at half the relative speed of the bearing surfaces. In bearing calculations the *mean* viscosity within the film usually is taken to be that of the whole film.



| $M$ | $F/\sqrt{\mu UW}$ | $c/\sqrt{\frac{\mu U}{W}}$ | $h_o/(l\sqrt{\frac{\mu U}{W}})$ | $h_m/(l\sqrt{\frac{\mu U}{W}})$ |
|---|---|---|---|---|
| 7.5 | 4.015 | .0313 | .2347 | .2503 |
| 10.0 | 4.593 | .0208 | .2080 | .2184 |
| 50.0 | 9.596 | .0021 | .1032 | .1042 |

Fig. 98. Effect of Deviations from Optimum Conditions for a Bearing with Flat Wedge Films

**THE FLAT WEDGE FILM** (Fig. 99).—A study of the flat wedge film by means of the Reynolds equations assumes the oil flow to be all parallel to line A-A in the direction of motion, although the actual flow follows the curved lines. See Kingsbury (5). The analysis discloses some important oil film characteristics. The stationary bearing surface may be assumed to be placeable in any desired relation to the upper or moving face, thus varying the relative proportions of $s$ and $l$ and the thicknesses $h_o$, $h_m$. The load $W$ per unit of width $b$, the length $l$ of the bearing face, the speed $U$, and the mean viscosity $\mu$, all may be assumed as fixed. It is assumed that the position of the support of the inclined face, if pivoted, may be altered at will to satisfy these imposed conditions. Three cases, limited to the conditions in which the influence of side leakage on pressure is negligible, as with infinitely wide bearings, are considered below:

**Case 1. Minimum Friction Condition.**—Frictional resistance to motion will be a minimum when $s/l = 0.484$. Film proportions then will be $h_m/h_o = (s + l)/s = 3.065$.

**Case 2. Optimum Load Condition.**—Film thickness at $h_o$ will be greatest when $s/l = 0.841$. This condition was determined by Reynolds. Film proportions will be $h_m/h_o = (s + l)/s = 2.190$.

**Case 3. Optimum Friction Condition.**—Friction, per unit of least film thickness $h_o$, will be minimum when $s/l = 0.652$. Film proportions will be $h_m/h_o = (s + l)/s = 2.533$. Kingsbury (5) has selected this as the *optimum friction condition* for flat-surface bearings.

The following discussion is based on the curves, Fig. 98, for which the above case data are critical points. They are plotted from the Reynolds equations. Case conditions are marked on curves having the same numbers.

The critical points of the curves are found to be so grouped that the range of variations of least film thickness and of friction does not exceed 4%. Case 3 is the best choice from the combined viewpoint of bearing efficiency and factor of safety, although any one of the case criteria would be reasonable.

**Deviations from Optimum.**—Side leakage effects are assumed negligible. Referring to Fig. 98, curve 1, the minimum friction conditions exist with a value of the ratio $M = s/l = 0.484$ (Case 1). Decrease of this ratio increases the angularity of the bearing faces, increases friction and decreases minimum film thickness $h_o$ (curve 2), tending toward metallic contact. Increase of the ratio $M = s/l$ tends toward parallelism of the bearing faces, increases the friction slowly, and decreases minimum film thickness $h_o$ more slowly. These changes bring the conditions closer to those of Cases 2 and 3. By means of tabulated figures at the top of Fig. 98, the curves can be extended beyond the limits of the chart to show friction coefficients, etc., in bearings with nearly parallel faces, far removed from the best. Thus when least film thickness $h_o$ (Curve 2) reaches a value one-quarter of the best value assumed in Case 2, the friction, $-F/\sqrt{\mu U W}$, is over five times the least obtainable. Nevertheless, if great care is used in making and maintaining the bearing surfaces, they might run with perfect lubrication and without wear.

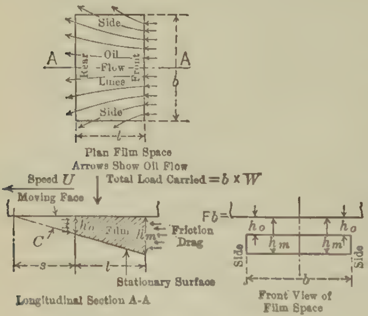


Fig. 99. The Flat Wedge Film

Side leakage correction factors set up for optimum conditions may be used with a fair degree of accuracy for quite different proportions, if the deviation is in the direction of near parallelism of bearing surfaces.

**THE CURVED WEDGE FILM.**—Oil film shapes in journal bearings, when geometrically accurate and simple, are of two forms, *i.e.*, clearance bearing films and fitted bearing films. Both may be expressed by a sine curve equation and shown in developed section when the journal is represented by a straight line. See Figs. 100 and 101. For comparison, the angular extent $\beta$ of the bearing is made equal to the length $l$ of the flat wedge film, Fig. 99. Film thickness at entering end is denoted by $h_E$; that at leaving end by $h_L$.

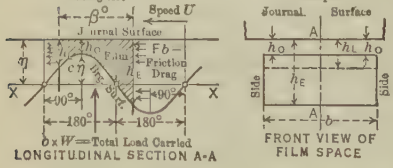

Fig. 100. Curved Wedge Film of Clearance Bearing

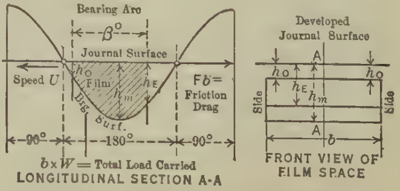

Fig. 101. Curved Wedge Film of Fitted Bearing

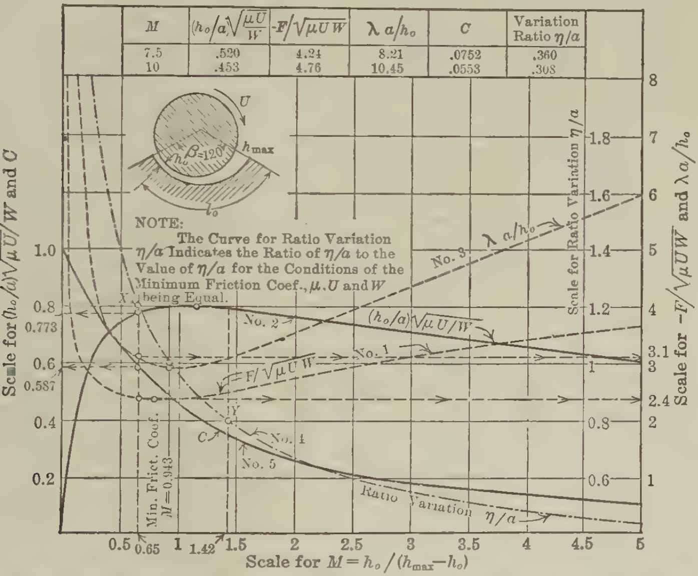
**Clearance Bearing Films** (Fig. 100).—The sine curve axis is placed at a distance $\eta$ = radial clearance from the sine curve median line X-X. If $c$ = eccentricity factor, minimum film thickness $h_o = \eta - c\,\eta = \eta\,(1 - c)$. Thickness $h_E$ may be less than maximum film thickness for some film proportions.

**Fitted Bearing Film** (Fig. 101).—The running clearance is zero. Angular contact $\beta$ cannot much exceed 90 deg., and $\beta$ = 180 deg. is geometrically impossible. Maximum film thickness $h_m$ is apt to be in the film, and not at the entering end. Minimum film thickness will be at the far end of the film, *i. e.*, $h_o = h_L$.

**Optimum Conditions in Journal Bearings.**—See discussion, tables and curves relating to optimum bearing classes A, B and C in Loading and Friction of Journal Bearings, pp. 13–18 to 13–25.

**General and Special Conditions.**—See discussion, general tables and charts for Classes C, D, E and F, Loading and Friction of Journal Bearings, pp. 13–24 to 13–28.

**Deviation from Optimum.**—Many series of journal bearing films are possible. The present study is limited to a centrally-loaded 120-deg. clearance bearing. The film is assumed to be a curved wedge, Fig. 102, extending from $h_{\max.}$ at the entering edge to $h_o$ where the film thickness is least, for which the wedge length is $l_o$. Length $l_o$ usually will be a little less than 120-deg., depending on operation conditions.



| $M$ | $(h_o/a)\sqrt{\mu U/W}$ | $-F/\sqrt{\mu U W}$ | $\lambda\, a/h_o$ | $C$ | Variation Ratio $\eta/a$ |
|---|---|---|---|---|---|
| 7.5 | .520 | 4.24 | 8.21 | .0752 | .360 |
| 10 | .453 | 4.76 | 10.45 | .0553 | .308 |

Fig. 102. Effect of Deviation from Optimum Friction Coefficient Conditions in a 120-deg. Clearance Bearing

Fig. 102 is a series of curves, showing the relation of certain dimensionless groups in a 120-deg. centrally-loaded bearing, which will be useful in arranging tolerances for journal and bearing diameters. The curves which are plotted against a scale of $M = h_o/(h_{\max.} - h_o)$, are as follows: 1, Friction drag, $-F/\sqrt{\mu U W}$; 2, Bearing capacity, $h_o/(a\sqrt{\mu U/W})$; 3, Friction coefficient, $\lambda a/h_o$; 4, Clearance ratio $\eta/a$; 5, Eccentricity factor $c$. See p. 13–15 for notation. Curves 1 to 3 correspond to those with the same numbers in Fig. 98. The application of the curves can be illustrated by an example.

Example.—Determine the effect of an increase of 20% and a decrease of 20% in clearance ratio from optimum for optimum friction condition of a 120-deg. clearance bearing.

*Solution.*—Minimum friction is shown by Curve 3 to correspond to a value of $M$ = 0.943. Optimum clearance ratio $\eta/a$ corresponding to this has been taken as unity in plotting Curve 4. An increase of 20% corresponds to point X on Curve 4 with a corresponding value of $M$ = 0.65. The ordinate through X intersects the other curves to give the following values: Friction drag, Curve 1, 2.4; bearing capacity, Curve 2, 0.773; friction coefficient, Curve 3, 3.1; eccentricity factor, Curve 5, 0.587.

A decrease of 20% in clearance ratio $(\eta/a)$ corresponds to the point Y on Curve 4, with a corresponding value of $M$ = 1.42. From the intersection of this ordinate with the several curves, the following values are found: Friction drag, 2.53; bearing capacity, 0.788; friction coefficient, 3.1; eccentricity factor, 0.348.

The tabulation above Fig. 102 permits the extension of the curves beyond the limits of the chart. With a value of $M = 10$, the other values are such that an accurately made bearing would function properly with pure film lubrication.

The curves of Fig. 103 have been derived from those of Fig. 102 to show more directly the influence of deviation of clearance ratio from optimum. Small deviations have little influence, but if clearance ratio variation is large, the efficiency of the bearing is sensibly affected, especially if clearance is reduced. The friction coefficient factor increases more with a reduction of clearance ratio than with an increase. If it is not feasible to design a bearing with a clearance ratio corresponding to optimum conditions, a larger rather than a smaller clearance ratio should be provided. The relation of curvature to safety of starting and stopping under heavy loads should not be overlooked, as it leads in the other direction, *i.e.*, the choice of a smaller clearance, or to the fitting of a portion of the bearing surface to the journal. (See Curve 4.)

**EFFECT OF SIDE LEAKAGE.**—The influence of side leakage on the capacity of a perfectly lubricated thrust bearing, and other bearings with wedge-shaped films, is considerable. Fig. 104 compares the results of several investigators. Abscissas are ratios of (length/width) *i.e.*, $l/b$. Ordinates are capacity factors $L_1$, which show the percentage of the *ideal load* that can be carried on a film with finite dimensions of length and width. The ideal load with which the bearing of finite length and width is compared, is one of the same finite length $l$ (in direction of motion), but which is understood to be a part of one whose width $b$ is so great (infinite) that there is no side leakage to reduce the capacity. The points determined by Michell (9), by Martin (10), and by Duffing (12), apply to a flat wedge film whose proportions are two to one, *i.e.*, $h_m/h_0 = 2.0$. Kingsbury extended the investigation to cover curved wedge films such as occur in journal bearings of the fitted and clearance types. The correction factors in Fig. 38 were developed from this study.

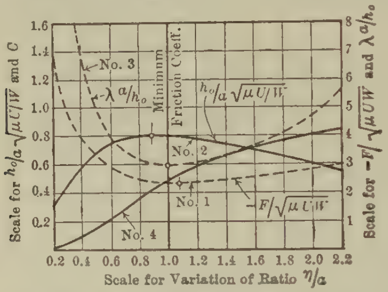


FIG. 103. Effect of Deviation from Optimum Friction Coefficient Conditions in a 120-deg. Clearance Bearing

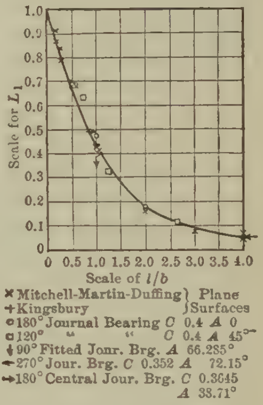

FIG. 104. Influence of Side Leakage on Carrying Capacity of Oil Film as Determined by Analyses of Michell (9), Martin (10), Duffing (12), Kingsbury (6).

## 7. MISCELLANEOUS BEARINGS

Study of the oil film type of journal bearing has indicated the possibility of their successful application within dimensions identical with those now used for ball and roller bearings. In the Nomy bearing, separate pivoted shoes are mounted on a ring that revolves with the shaft. The shoes bear on the inside of a stationary outer race. Provision is made for automatic lubrication. The Fast bearing has shoes integrally formed on the inner ring and connected thereto by stems. The bearing is quite rugged.

In neither of these bearings is the revolving element integral with the shaft. It, therefore, must be carefully fitted and clamped against the shaft, usually against a shoulder, and keyed or otherwise held to prevent slippage at starting. Otherwise these bearings are mounted in the same way as ball or roller bearings. A comparison of a bearing of this type and the more usual construction in which a bearing shell about one diameter long supports the shaft journal directly, shows the space occupied to be about the same in both cases for similar service. Manufacturers should be consulted for detailed information.

**ROLL-NECK BEARINGS.**—Roll necks in mills have long presented a serious problem, especially in steel mills. Early practice, still widely followed, was crude and very wasteful of power. The bearings were undependable. Wear on necks and bearings was considerable. The bearing equipment acted as a bar to the construction of larger mills. To remove this handicap, anti-friction bearings have been used with considerable success, but exhibited certain limitations. Since 1930, the oil film type of bearing has been successfully applied to roll necks. One of these, the Dahlstrom roll neck bearing, marketed by the Morgan Construction Co., Worcester, Mass., under the trade name of Morgoil Bearing, is described in *Trans.* A.S.M.E., IS 55–2, 1933.

The Morgoil bearing comprises a ground and polished steel sleeve or journal fitted over the roll neck, the latter being tapered at an angle of about 12 deg. The journal thus can be removed easily from the neck, which also can be made of larger diameter than is ordinarily possible. The sleeve is keyed to the neck. The bearing comprises a casing, into which is inserted a steel or bronze liner, faced with centrifugally-cast babbitt. Oil for lubrication is pumped into the bearing through holes in the casing, and flows through appropriate grooves to a drain pipe. Tests described in the paper above cited show this bearing to be capable of withstanding loads in excess of the roll-neck strength, and to effect considerable savings in power.

In Kingsbury roll-neck bearings installed on a wide strip mill of the Inland Steel Co., 1933, load was carried directly on the neck of the roll. The bearing shell was water-cooled. Oil was fed to the bearing by a gravity system to make up leakage at the seals. High-pressure oil was introduced to reduce starting friction, permitting operation at any speed, irrespective of the load on the bearings. The friction was about the same as for roller bearings for all conditions.

**OILLESS BEARINGS.**—Although bearings are offered that are lubricated by other media than oil or grease, it is assumed here that the term Oilless Bearing applies only to bearings to which no lubricant is expected to be applied. These comprise a wide variety of bearing shell materials with which lubricating substances are combined by one means or another in the process of manufacture. Among these are: 1. Fiber, plain or impregnated with lubricant; 2. Wood, plain or impregnated with lubricant, or with cavities filled with hard lubricant; 3. Special highly graphitic alloys; 4. Metal bushings with insets of hard lubricant; 5. Press-moulded mechanical mixtures of bearing materials and lubricants. Some of these materials will carry light loads at moderate speeds without serious wear. They are best suited to intermittent service or for very low speeds. Manufacturers should be consulted for detailed information concerning them.

## 8. BEARING MATERIALS

**METALS.**—**Hardened Steel** will work well on hardened steel at low speed under very heavy loads. It is fairly durable even if imperfectly lubricated. The same metals work well at high speeds when carrying moderate loads if well designed, finished and lubricated. Hard-surface bearings are least subject to abrasion by operation under adverse conditions. They are much used for small parts, but are too costly for large ones.

**Gray Cast Iron** is useful for bearing faces, especially if chill-cast. For moderate loads, such iron is excellent for both bearing surfaces, even for high-speed bearings, if properly lubricated. Cast iron works well with softer bearing materials, as babbitt metals and bronzes when properly lubricated, and can be made to carry high pressures.

**Soft Steel** will run well with babbitt metals and other white metal bearings, and will carry considerable pressure if properly lubricated. It also will run directly on cast iron. Soft steel on soft steel is not recommended, because of the tendency to seizure. Hard steel on soft steel sometimes is useful. A carbon content of 0.30 to 0.40 is recommended for shafts running on soft metal bearings. Soft copper-base alloys containing lead are useful for moderate speed and heavy pressure. There is a tendency, however, to line brass and bronze bearings with a thin coating of white bearing metal. This avoids the tendency of high-copper alloys, when overheated in bearings, to destroy the finish of the opposing cast-iron or steel surface by roughening, plating it, or producing surface cracks.

**Bearing Metal Alloys** are discussed more fully on pp. 4–62 to 4–67. In general, they are classified as bearing bronzes and babbitts. A more exact classification is low-lead bronze, high-lead bronze, lead-base, and tin-base bearing metals. In the last group is the bearing metal produced by Isaac Babbitt, containing Sn, 83 $^1/_3$, Sb, 8 $^1/_3$, Cu, 8 $^1/_3$. This alloy, and others with varying compositions of the same metals, still are called Babbitt Metal. Kingsbury uses a composition of Sn, 85, Sb, 10, and Cu, 5. The U. S. Navy composition is Sn, 88 $^1/_2$, Sb, 7 $^1/_2$, Cu, 4.

**Non-Metals.**—*Fiber* (pressed paper) washers often are used for thrust bearings for low speed and considerable load, or high speed with light load when oil lubricated. *Jewels* or ruby or other crystals are used with hardened polished steel pivots in timepieces and instruments, oil lubricated. *Ivory* bushings are found in the best old clocks, with hardened steel pivots. *Hardwood* bearings have been used, lubricated by tallow and soaps.

**Lignum Vitae.**—In the best applications lignum vitae is used with grain perpendicular to the bearing face. It is used to line stern tubes of ships, with fresh or salt water lubricant. The bearing in a vertical-shaft hydraulic turbine often has a lining of lignum vitae blocks in longitudinal grooves in the bearing shell. Adjustment is required to compensate wear. In this service they are lubricated with fresh water. Lignum vitae has been used in footstep bearings under water in water-wheels.

**Rubber** is used to line bearings where only water is available as lubricant and where bearing pressure is light. It is useful in guide bearing bushings for vertical revolving shafts, and in stern tube bearings in ships.

**Resin-bonded Bearings.**—Mr. L. M. Tichvinsky of the Westinghouse Elect. & Mfg. Co. gives the following résumé of literature on this bearing material:

The rapid development of the phenolytic or resin-bonded bearings was directly connected with the steel mill industry. According to their structure and manufacture, the synthetic resin-bonded bearings can be classified into three groups: 1. Manufactured from plain or graphitic molding powders; 2. Manufactured from various felts of impregnated non-oriented fibers; 3. Manufactured from laminated products.

The bearings of Group 1 are manufactured in great quantities for low load application, and for guide bearings of high-speed machines. High brittleness limits their application.

Due to different bases, bearings of Group 2, are tougher and more rigid than the bearings of Group 1. Their application is also for low or medium loads. Group 3 covers the most important type of bearings bonded with synthetic resin. They also are called laminated bearings because of their base consisting of woven textile fabrics. Occasionally, for less important performances, they are made from laminated paper products. In manufacturing these bearings high pressures and high temperatures are applied for a predetermined period of time during which the powdered synthetic resin liquifies. On cooling, a well-bonded product is obtained. These bearings are marketed under various trade names.

For more severe operations, as in steel mills, these bearings perform most efficiently with water alone for both lubricating and cooling. The average physical and mechanical properties of a good laminated bearing material are as follows: Specific gravity, 1.25 to 1.40; weight (approx.), 0.05 lb. per cu. in.; Brinell hardness, 30–42; tensile strength, lb. per sq. in. (along grain), 8,000–15,000; (across agrain), 6,000–11,000; modulus of elasticity, 1,000,000; compressive strength, lb. per sq. in., (perpendicular to laminae) 40,000–45,000, (parallel to laminae), 20,000–24,000; water absorption, 7-day test, 1–3%; oil absorption, negligible.

## 9. MAKING AND FINISHING OF METAL BEARING SURFACES

**ANCHORING.**—For holding a soft metal lining to harder bearing surfaces the ordinary dovetail circular anchor is much used, but the T-head anchor is better because shrinkage of its neck holds the metal faces together. Anchors should be small and sparingly used, because they remove the backing of the soft bearing face by shrinking away from it. Sometimes they are omitted entirely. Small T-slot grooves are useful, especially if machined. Simple anchors sometimes are formed by a drill point, or by plain grooves.

**TINNING.**—In order that heat may pass freely from the bearing lining to its backing, the latter often is tinned. The surface to be tinned should be machined or ground smooth and must be clean. The shell should be heated, flux applied, and the tinning metal then spread thoroughly by scrubbing. It is best to tin the surface with the lining material. Usually with the residual preheat the shell is then ready to receive its soft metal lining. Some metals tin more easily than others. Steel and ordinary bronze are more easily tinned than cast iron and the aluminum- and other special bronzes. Copper plating before tinning improves the bond.

**PEENING.**—The value of peening or burnishing in the preparation of soft metal bearing faces is an open question. The resulting texture may be less uniform, even though sometimes harder. Peening holds the lining tightly to dovetail anchors, but peening a face that has been applied to a tinned surface is apt to loosen the tinned bond. Some alloys are hardened more by peening or burnishing than are others.

**FITTING UNDER LOAD** is useful for large vertical thrust bearings, and often is used to compensate deflections produced by loads. In this process, a few turns at very low speed are made to spot the softer surfaces by the harder. A fairly heavy coating of lubricant will prevent overheating during the process. The hard face then is lifted and the rubbed spots on the soft face scraped down lightly. High spots on the harder face may be reduced by fine stoning. Usually all fitting is done on the softer face. The process is repeated until a fit of the desired extent and accuracy is obtained. The oil used with this fitting should be only heavy enough to get the desired marking on the bearing surface without injury or waste of time.

**RUNNING-IN** of bearings often is used as a system of inspection or of preliminary service. It sometimes is rather brutal, the journal being used to ream or burnish the bearing. It should not be taken as a substitute for good design and workmanship. See

Fitting under Load, above. Running-in, if carefully done, will improve the bearing surface smoothness. It may be used in lieu of fitting under load with small machines. It is best, however, to pre-machine the bearing elements as nearly correct as possible, and to use designs and clearances suitable for immediate service.

**FORMING.**—The hardest surfaces can be finished by grinding, and softer materials by machining, grinding or scraping. The smoother and truer the surface the better will the bearing operate with proper lubrication. Lapping, after grinding, or over a smooth tool finish, is one of the best ways to produce accurately cylindrical, flat, or spherical surfaces on steel and cast iron. See p. 21–87. Final finishing may be by rotation under a lightly pressing block of wood faced with leather, using fine abrasive and oil. Scraping, stoning, and filing are all useful for finishing and for fitting one surface to another. Smooth file finishing on a revolving a shaft is common, but it will not true a surface initially out of round. Careful final finishing or fitting of the bearing surface is essential. A very smooth and accurate tool or grinder finish may not need further treatment. In important work, fitting of the softer bearing surface to the other or to a master surface by hand scraping is common. Thus, a bearing may be fitted to a mandrel of a diameter equal to that of the journal plus the desired running clearance.

## 10. LUBRICATION OF BEARINGS

Bearings are lubricated by the following systems: 1. Automatic; 2. Intermittent; 3. Bath; 4. Splash; 5. Pressure; 6. Mechanical.

**AUTOMATIC LUBRICATION.**—The rotation of the shaft causes oil to be fed to the bearing surfaces. Lubrication ceases when the shaft stops turning. The systems in common use are: Ring oiling, chain oiling, disc oiling, capillary oiling, waste pack oiling, vacuum oiling, and oiling by means of a shaft-driven pump of any type. All these systems lift oil to the bearing from a well below it, and are capable of continuous operation for long periods, because oil leaking from the ends of the bearing or elsewhere returns to the well and is used over again. See Figs. 20 and 28.

**INTERMITTENT LUBRICATION.**—Oil is applied to the bearing at intervals from a source independent of the rotation of the shaft. The simplest, but least dependable system, is hand oiling from an oil can. Cup oiling is better, as it has the possibility of being practically continuous and uniform, with visible and adjustable rate. Wick oiling, with textile or metal wicks, is, next to hand oiling, the simplest and cheapest system. The number of wick strands determines the rate of supply. The wicks filter the oil. The general faults of intermittent systems include usually complete loss of oil after it leaves the bearing, frequent refilling of cups and wells, and inadequate, or wasteful oiling by reason of ignorance or carelessness.

**BATH LUBRICATION.**—The bearing faces are completely immersed in a bath of oil at all times. This system frequently is used for vertical shafts, and is simplest for the lower end of the shaft, where thrust and radial bearings can be combined. At other places on the shaft, the well may be formed by a revolving bowl, or the well may have a tube that extends upward around the shaft, and inside of a sleeve that extends downward from a hub to form the journal of the radial bearing. See Fig. 31. This last system is commonly used for thrust bearings placed anywhere along a vertical shaft. Packing may be used in stuffing boxes to hold oil in any kind of a recess about a bearing, horizontal or vertical, that will make it a bath-oiled bearing. Oil will leak away, even though slowly, from such a bearing. There also is the danger of setting up the packing so tightly that it will run hot and the shaft will be worn within it.

**SPLASH LUBRICATION** was common in the crank cases of internal combustion engines and still is considered a simple way to oil all the bearings of a trunk-piston engine. The splash is produced by the lower ends of the connecting rods dipping into the oil in the crank case. Various refinements are used to control the splash. This might be considered a continuous system, because most of the oil is returned to the crank case to be used again, although partly contaminated or broken down by exposure to cylinder walls. The system is used in compressors and other crank machines.

**PRESSURE LUBRICATION.**—Pipes lead oil to the bearings from a source of oil under pressure. The pressure is available at the point of application of oil to the bearing and will therefore tend to keep oil passages open. Bearings with this system usually are simple when the whole machine is so enclosed that oil will drain to the sump from which an oil pump redistributes it to the bearings. The rate of oil supply to each bearing may be regulated by making the size of the supply hole to suit the pressure in the system. The source of oil may be independent of the operation of the machine, as when a separate motor-driven oil pump is used. It may otherwise be driven by some shaft in the machine, and, therefore, operates only when the machine is running. Each method has its drawbacks, and judgment must be used in selection.

**MECHANICAL OILERS.**—A variety of mechanical devices are on the market for producing what may be styled centrally-controlled, intermittent-lubrication of bearings. They eliminate oil cups, but introduce a multitude of small oil pipes, through which oil is fed or forced intermittently, in measured amounts. These devices usually operate by ratchets driven from the shaft of the machine whose bearings they oil.

**COOLING OF BEARING OIL.**—To keep oil in a bearing at a safe temperature, the heat of friction due to operation must be dissipated. Safe temperature depends on the kind of oil used and the conditions against which the bearing must be protected. Thickness of oil film and heat of friction both increase with viscosity of oil.

**Direct Air-cooling.**—The oil housing surrounding the bearing should be sealed tight to prevent leakage. The oil then is allowed to warm up sufficiently to dissipate friction heat to the surrounding air by radiation and convection. As the oil heats it becomes less viscous and the friction loss in the bearing decreases. The rate of radiation and convection increases as the oil gets warmer. When heat generation and heat dissipation become equal the oil temperature will remain quite uniform, being affected only by changes in the surrounding air temperature. In air-cooled bearings the oil level should be watched and new oil added, as required, to replace that lost by leakage and evaporation.

**Direct Water-cooling** is applied in three ways: 1. Water-cooling coils in the oil within the housing; 2. Water-cooled shoes; 3. Water-cooled collars. With all of these applications water must be circulated fast enough to remove the heat of friction from the oil and keep it at a safe temperature. Means must be provided to prevent leakage of water into the oil, and leakage of oil from the housing. New oil must be added from time to time to make up loss from leakage and evaporation. When water-cooling coils are used in the housing, the oil should have a pour test point considerably lower than the temperature of the coldest cooling water, to prevent congealing on the coils.

**Self-contained Unit Circulating System.**—Each machine in which a bearing is installed has an individual oiling system that circulates oil through all bearings. Within the system are means for air cooling or water cooling the oil, depending on the amount of friction heat to be dissipated. When the pump is driven directly by the machine itself, oil supply to the bearings begins when the machine is started. Hence, if the oil in the bearing housing has leaked away during a shut-down and exposed the rubbing surface, the bearing will burn out before the pump has supplied enough oil to bring its level up above the bearing faces. This danger must be removed by inspection before starting the machine. Siphoning of oil back through the inlet pipe should be prevented by placing its opening above the oil level, or by providing an air vent hole.

**Central Station System.**—With this system oil should be circulated through the housing of each bearing at the rate recommended for each case, to lubricate the bearing and carry away the friction heat developed. The piping in such a system often is so extensive that the oil will be sufficiently air cooled in making the circuit. When necessary, however, the system is provided with water-cooling coils in the central station.

# LUBRICANTS

By J. C. Geniesse.

A lubricant is a liquid or soft solid substance, as oil, grease or graphite, interposed between moving parts to reduce friction and wear. Liquids are almost universally used where rubbing or bearing surfaces are designed to retain most of the lubricant within an enclosed system. Greases and solids are used where leakage is too high to retain liquid. The most important property of a liquid lubricant is its viscosity at normal operating temperature, since it determines the friction and whether there shall be any wear. All other requirements imposed on a viscous lubricant are to insure that it remain chemically inactive under all conditions of operation for a reasonable length of time. Requirements for liquid, plastic and solid lubricants are the same, *viz.*, that they must produce low friction and wear. These requirements are not so easily defined in terms of properties of the plastic and solid lubricants, since they usually are used where metal-to-metal contact is inevitable, and where wear is almost unavoidable.

## 1. TYPES OF LUBRICANTS

**MINERAL OILS.**—Lubricating oils of petroleum origin are almost universally used, because of availability and stability. They are complex mixtures, primarily of many hydrocarbons. Eastern base, or Pennsylvania oils, contain a large proportion of paraffin hydrocarbons; Western base oils generally contain more naphthene and less paraffin hydrocarbons. Lubricating oils from Midcontinent crudes lie between these extremes. Coastal oils from states adjoining the Gulf of Mexico may be similar to those from California or the Midcontinent area. Specific gravity, and change of viscosity with both temperature and pressure, are lower for paraffin than naphthene type oils. Carbon residue, color and heat stability depend more on type and degree of refining than on source of the oil. However, by means of solvent and other special methods of refining, naphthenic and unstable compounds may be removed from a lubricating stock, leaving a fraction predominantly paraffinic. The paraffinicity of a naphthenic or mixed-base lubricating stock may be increased, producing an oil of viscosity and gravity equivalent to those of Pennsylvania oils.

**ANIMAL, VEGETABLE AND FISH OILS** frequently are called fixed oils, because they are not volatilized without decomposition. Distillation causes them to decompose, leaving a carbonaceous residue. The oils most frequently used are: *Animal*, lard, tallow, neatsfoot; *Fish*, sperm; *Vegetable*, castor and rape seed. With the exception of sperm oil they consist mainly of glycerides of saturated and unsaturated long-chain acids. Sperm oil is chiefly myricyl palmitate, a long-chain ester of a monohydric alcohol. All contain unsaturated compounds which oxidize more easily than petroleum oils. This fact has retarded their general use at high temperatures.

Fixed oils adhere more tenaciously to metal than straight mineral oils. Consequently, they are used for compounding purposes where water vapor has a tendency to condense on bearing surfaces. Where humidity is high, as in marine service, most oils are blended with 5 to 10 % of fixed oil to overcome the detrimental effect of water. They have better viscosity-temperature slopes than mineral oils, and are used as a medium for introducing other agents, as sulphur, since they have greater solubility and chemical affinity for such materials.

**GREASES,** in general, are mixtures of mineral oil and soap. Other compounds, as fixed oils, graphite, etc., may be introduced to obtain specific properties. The soap reduces flow or loss of lubricant. In general, viscosity of the mineral oil is chosen on the assumption that no leakage will occur; the soap then is added to prevent leakage. At high rates of shear, friction offered by a given grease is not much higher than that of straight oil of the same viscosity as that incorporated in the grease; at low rates of shear friction is considerably higher.

**MISCELLANEOUS.**—Graphite, wax, soapstone and other soft solids are used for lubrication, particularly where rubbing speeds are low, and where the type of construction makes it difficult to retain lubricant on bearing surfaces. Water also has been used extensively for lubricating bearings. Steel mill roll-necks with bakelite or other resin bearings can be lubricated quite successfully with water. If operation is intermittent, the water must be removed when not in use, to avoid excessive corrosion.

## 2. PROPERTIES OF LUBRICANTS

**VISCOSITY.**—All lubricating oils decrease in viscosity as temperature increases, the relation being complex. The A.S.T.M. has published charts for both kinematic and Saybolt viscosity whose scales are constructed to give straight lines when data are plotted on them. See Fig. 107. Paraffinic oils change less with temperature than do naphthenic oils; vegetable and animal oils vary still less.

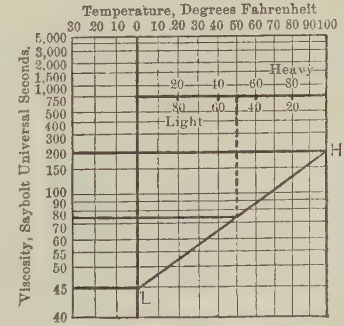

Fig. 105. Viscosity Blending Chart

Viscosity usually is measured at temperatures of 100°, 130° or 210° F. in the Saybolt instrument; the time in which a given volume of oil flows through an orifice under specified conditions is taken as the viscosity. More recently, capillary kinematic methods have been developed to measure viscosity more accurately. Refer to latest A.S.T.M. Standards for detailed procedure. Various attempts have been made to numerically express the viscosity-temperature slope for purposes of convenience. Dean and Davis use an index of 100 for Pennsylvania oils and 0 for extremely napthenic oils. On this scale, Midcontinent oils average 75. See Fig. 107 for a convenient graphical method for estimating the viscosity index of lubricating oil.

Blending often is employed to produce oils with intermediate viscosities. Fig. 105 illustrates the procedure generally used to predict the viscosity of a blend. Any 100° temperature range on a viscosity-temperature chart may be used for this purpose, if the upper and lower temperature limits are used, respectively, for the heavy and the light components.

All oils also change markedly in viscosity when high pressures are imposed on them.

Hersey has shown that the equation $\log (Z_1/Z_0) = K_1P + K_2$ may be used to depict this relationship. In this equation, $Z_0$ = viscosity at atmospheric pressure; $Z_1$ = viscosity at pressure $P$; $K_1$, $K_2$ = constants. Paraffinic oils vary less with pressure than naphthenic oils, and fixed oils still less.

**CONSISTENCY** defines the resistance to shear of plastic substances, as grease, just as viscosity is applied to viscous liquids. Consistency of grease varies both with temperature and rate of shear. At high rates of shear the consistency is lower than at lower rates. Consequently, the force required to shear grease in a given bearing does not decrease proportionately with speed. This permits use of a product that does not readily leak, and yet offers small resistance to shear at high speeds. Consistency ordinarily is measured by a penetrometer. A double-pitched cone of standardized weight and dimensions is dropped into the product, maintained at a definite temperature. The depth of penetration, measured in hundredths of a centimeter, is reported as the penetration of the material. See A.S.T.M. Tentative Standards.

**SPECIFIC GRAVITY,** *per se*, is of no value in predicting quality of a lubricating oil, although it frequently has been used to determine or specify the source of the oil. It varies linearly with temperature. See Fig. 106. Paraffinic oils are the lightest; naphthenic, intermediate, and the animal and vegetable oils the heaviest. Compounding, particularly with lead soaps, increases specific gravity of oil.

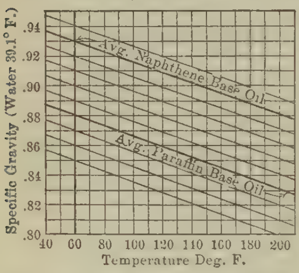

Fig. 106. Variation of Specific Gravity with Temperature of Oil

**POUR TEMPERATURE** of an oil is the lowest temperature at which it will flow, under conditions prescribed by A.S.T.M. It is used to predict the lowest temperature at which an oil will flow freely to bearings or oil pump. Paraffinic and some naphthenic crudes contain wax which congeals at low temperatures, and must be dewaxed for use in cold weather.

**FLASH AND FIRE.**—The A.S.T.M. flash point is determined by heating the oil in a vessel under prescribed conditions until sufficient vapor is driven off to flash when exposed to a flame. A.S.T.M. fire point is the temperature at which sufficient vapor is given off to give a continuous flame. Only under unusual circumstances are fire and flash points of value in predicting quality of an oil, except to indicate its source. In general, flash and fire points of paraffinic oils are higher than those of naphthenic oils.

**COLOR** of lubricating oils is determined in the A.S.T.M. Union Colorimeter by comparing the density of light transmitted through the oil with that transmitted through glass color standards. An arbitrary scale of 0 to 8 is used to designate color. Commercial crank-case oils range from 1 to 6 and heavy gear oils from 6 to 8. Color is of value only to determine the extent of refining, when considered in conjunction with the source, since naphthenic oils are, in general, lighter than paraffinic oils. Solvent refining methods, however, have upset the value of color as an indicator of degree of refining.

**CARBON RESIDUE** is percent of residue remaining after destructive distillation of a weighed quantity of oil under prescribed conditions. It originally was developed to compare carbon-forming qualities of lubricating oils for internal combustion engines. Correlation of laboratory tests with engine tests has been only moderately successful. Modern refining methods tend to make this test less useful for predicting carbon-forming tendency of motor oils.

## 3. LUBRICATING OIL REQUIREMENTS

**INTERNAL COMBUSTION ENGINES.**—Requirements of crank-case lubricating oil are more difficult to meet than those of most lubricants, because of the wide range of temperatures to which it is subjected. At the lowest atmospheric temperatures, viscosity must be below 40,000 Saybolt seconds in order that starting torque be within the capacity of the starting motor. At the highest operating temperatures, which may be 300° F., it must have sufficient viscosity to maintain an oil film in the bearings. No lower limit of viscosity has been established, and probably would have no practical value, since oil consumption, which depends on viscosity under a given set of conditions, becomes excessive before bearing failures develop. This should not be construed to mean that viscosity is the controlling factor determining consumption. Motor speed, and mechanical condition, are responsible for far greater variations.

To simplify lubricating oil viscosity requirements, the S.A.E. has promulgated a viscosity classification to cover atmospheric temperatures and types of operation ordinarily encountered. The ranges (see Fig. 107), are classified at low temperatures for winter oils and higher temperatures for summer oils.

Pour point must be approximately equal to or below the lowest anticipated atmospheric temperature, to assure uninterrupted supply to pump and cylinder walls.

For reasonable life of oil it must not oxidize so rapidly as to form sludge or carbonaceous matter which ultimately may interfere with lubrication. There are no infallible quantitative tests for this determination, but almost any well-refined product marked by a reliable concern is satisfactory. Carbon deposits in combustion chamber and on valves are not so serious a problem as in the past, since refining methods have made possible the marketing of oils which deposit very little carbon in combustion chambers.

**GEARS.**—The requirements for gear lubricants depend on load and speed of the gears, and on construction of the gear box. If load and speed are not very high, oils of viscosity of 80 to 200 Saybolt sec. at 210° F., depending on operating temperature, are generally recommended. If the gear box is not tight enough to prevent leakage, oil of the same viscosity should be incorporated in a grease. If speeds are high and gears machined to a good fit, oils in the range S.A.E. 20 to S.A.E. 40 may be used.

Many automotive rear axles operate at very high loads and with appreciable rubbing speeds. To avoid scoring, they must be lubricated with special products. Two types of oil have been developed: 1. Mild extreme pressure lubricants; 2. Powerful extreme pressure lubricants. They contain active chemicals which presumably act as anti-weld agents at points of excessive load. For hypoid gears, where rubbing speeds are high, more powerful lubricants, containing more active ingredients, are necessary. Extreme pressure lubricants should be free of insoluble foreign materials and have the same viscosities as those used on other gears.

Gears in an industrial establishment are designed to operate at high loads. It then is necessary to use mild extreme pressure lubricants. No rigid rule is applicable to determine the type of lubricant necessary for a given set of gears, but, in general, if wear is high, leading to frequent replacements, an extreme pressure lubricant is advisable.

**STEAM TURBINES.**—The most important requirement of a turbine lubricant is that it be sufficiently stable to avoid forming oxidation products which tend to form stable water-oil emulsions. No fool-proof laboratory test exists for predicting this quality. Experience is the best guide. The viscosities normally used range from 150 Saybolt sec. at 100° F. to 100 sec. at 210° F., depending on speed and operating temperature.

**AIR COMPRESSORS.**—Lubricating oils must not form large carbon deposits, particularly on valve seats. The resultant valve sticking may lead to hot spots which ignite the air-oil vapors causing an explosion that may be disastrous both to equipment and life. Fixed oils must not be used, except in small quantities, as they are prone to form carbonaceous residues. Viscosities normally used range from 250 to 750 Saybolt sec. at 100° F., depending on amount of compression and the resulting temperatures.

**STEAM CYLINDERS.**—Condensation of moisture during the expansion stroke in steam cylinders makes necessary the use of compounded lubricating oils, which are effective in the presence of water. If high superheat is used, little condensation occurs, and not over 5% of the compounding agent is necessary; 10% is advisable with saturated steam. Acidless tallow is the compounding material generally used, although many vegetable and animal oils are satisfactory. The function of the compounding agent is to form an emulsion with water which will be carried to the cylinder walls to form a tenacious lubricating film. Viscosities generally used range from 90 to 200 Saybolt sec. at 210° F.

**RAILWAY CAR JOURNAL** lubricants must not be too viscous at the lowest operating temperatures, or the cotton waste will not carry oil to the brasses. In general, summer oils should have a stable viscosity of approximately 225 sec. at 130° F., and a pour point of 32° F. Winter oils should be 175 sec. at 130° F., and pour at 0 to 10° F. Wear reduction of brasses is possible by compounding, but since they are easily replaced, it is generally believed that the increased cost of such oils is unwarranted.

## 4. THE SELECTION OF MINERAL LUBRICATING OIL *

In the discussion of bearing design the viscosity of lubricating oil has been emphasized. Viscosity varies with temperature, and the viscosity-temperature relation is not the same for all oils. These variations have been classified by means of the viscosity index numbers proposed by Dean and Davis (generally known as V. I. numbers). The V. I. number for paraffin-base oil averages 100 on the Dean and Davis scale, and for naphthene-base oils 0. Special oils are now available with V. I. numbers higher than 100. The relations of the viscosities to the Dean and Davis numbers, and to various classification scales and Saybolt Universal viscosities (S.U.V.), are given in the chart, Fig. 107.

---

* Contributed by H. A. S. Howarth.

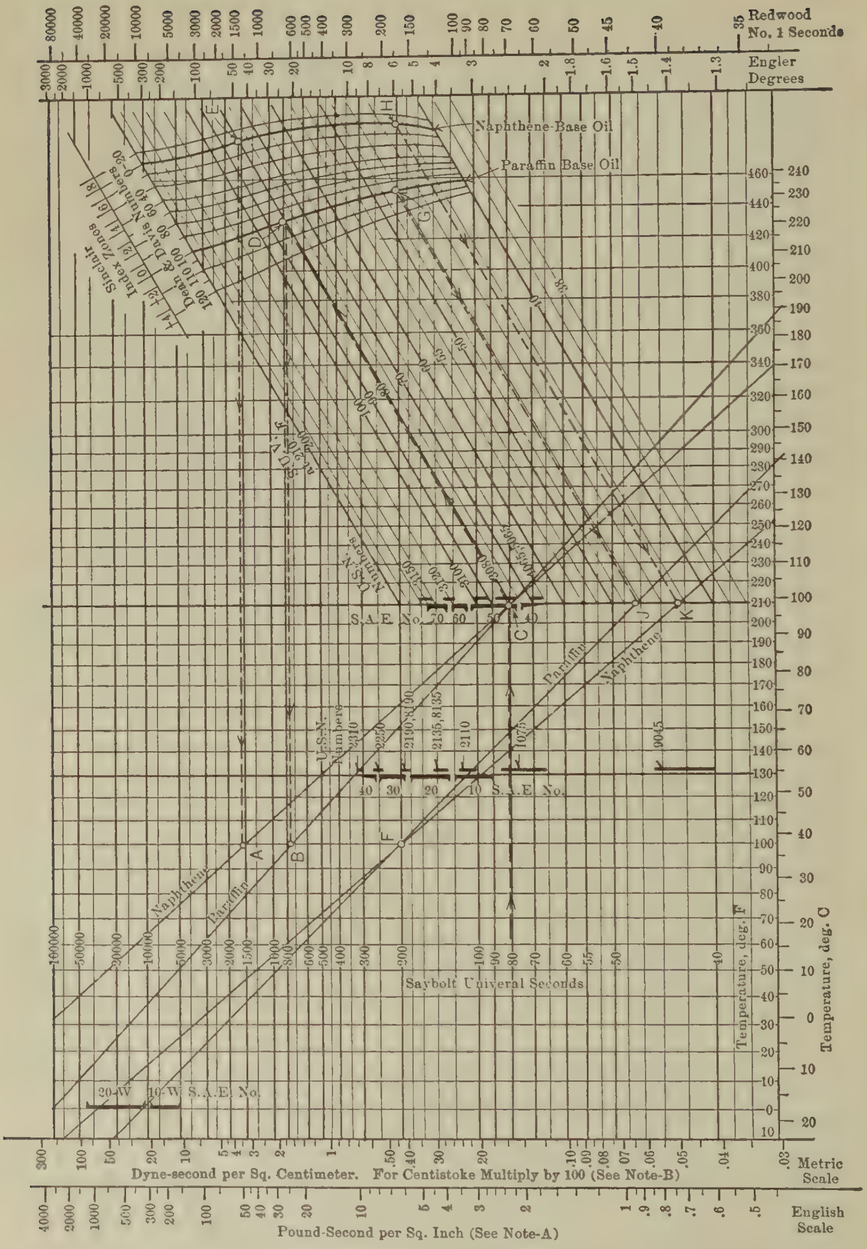

Fig. 107. Viscosity-temperature and Viscosity-index Chart

Note A. For absolute English viscosity coefficient (Reyns) multiply English scale reading by $10^{-6}$ and specific gravity referred to water at 39.1° F.

Note B. For absolute metric viscosity coefficient (poises or centipoises) multiply metric scale reading by specific gravity referred to water at 39.1° F.

Note C. For approximate Saybolt Furol seconds, take 0.1 × Saybolt Universal seconds.

Example 1.—Lay off viscosity-temperature lines for a naphthene- and a paraffin-base oil of the same viscosity, 80 Saybolt sec. at 210° F. Extend the line across the chart, Fig. 107. Note their relations to the various systems of oil classification. *Procedure.*—Follow the abscissa through 80 on the vertical scale of Saybolt Universal seconds until it intersects the ordinate through 210° F. at *C*. Follow the diagonal 80 on the S.U.V. scale at 210° F. upward to the right until it intersects the heavy V.I. = 100 line at *D*, and the V.I. = 0 line at *E*. The abscissas through *D* and *E* intersect the ordinate through 100° F. at *B* and *A* respectively. Draw lines through *B* and *C* and *A* and *C*, extending them across the chart. Line *AC* shows viscosity-temperature relation for the naphthene-base oil, and line *BC* shows it for the paraffin-base oil. Both will have the same viscosity, 80 S.U.V., at 210° F. At all temperatures above 210° F., viscosity of the paraffin-base oil will be higher than that of the naphthene-base. At all temperatures below 210° F. viscosity of the naphthene-base oil will exceed that of the paraffin base. The paraffin base oil lies in Navy Classification zone 2310 (on ordinate through 130° F.) Both oils will lie in Navy Classification zone 3080 (on ordinate through 210° F.). At 210° F., both oils lie in S.A.E. zone 50. At 0° F. both oils have viscosity above S.A.E. zone 10–W and 20–W (upper left corner).

Example 2.—Select an oil of viscosity 200 S.U.V. at 100° F. (point *F*, Fig. 107). The viscosity-temperature lines for the naphthene-base and paraffin-base oils satisfying this condition are determined as follows: Follow the abscissa through *F* (S.U.V. = 200) until it intersects the paraffin line V.I. = 100 at *G*, and the naphthene line for V.I. = 0 at *H*. From *G* and *H* follow the diagonals down to the left until they intersect the 200° F. ordinate at *J* and *K* respectively. Draw lines *FJ* and *FK*, extending them across the chart. Line *FJ* shows the viscosity-temperature relation for the paraffin-base oil, and line *FK* for the naphthene-base oil. The paraffin-base oil line crosses the 0° F. ordinate in the lower range of S.A.E. 20–W. At 130° F., it crosses S.A.E. zone 10, and U.S.N. zone 2110. The naphthene line crosses the upper range of S.A.E. 20–W at 0° F., and at 130° F. crosses S.A.E. zone 10 and lies between U.S.N. zones 2110 and 1075.

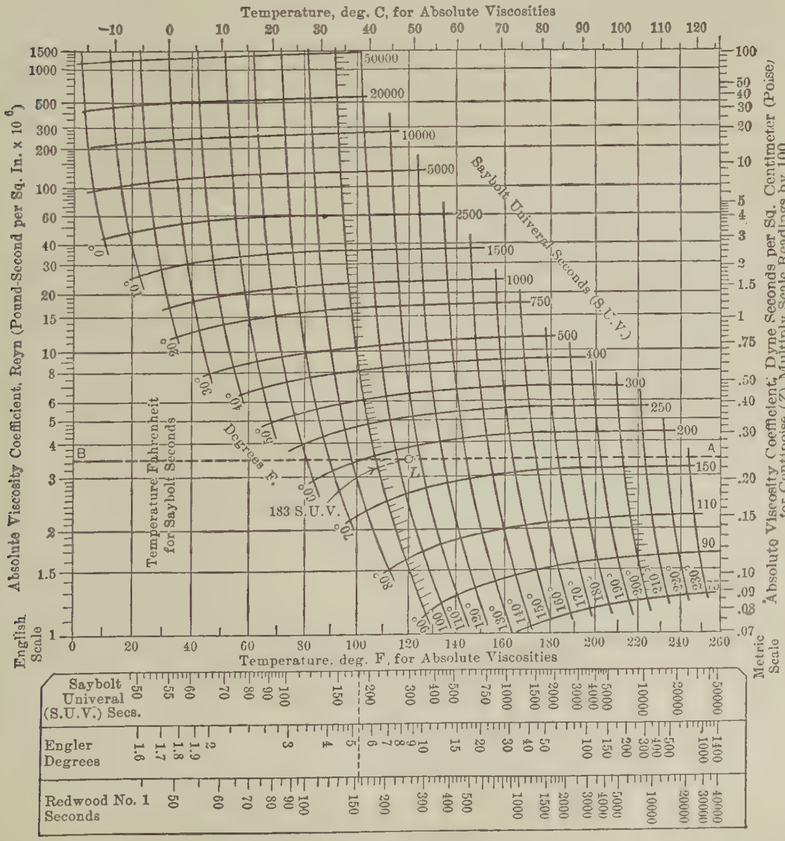

Fig. 108. Viscosity Conversion Chart for Mineral Oil Specification.

A study of Examples 1 and 2 show that if the naphthene and paraffin-base oils are selected at a given temperature to be identical in Saybolt viscosity, the viscosities will differ at temperatures above and below the temperature chosen, irrespective of the temperature used as a basis for comparison.

Saybolt viscosity is not a true measure of the friction-producing quality and load-sustaining value of oil, both of which depend on the specific gravity of the oil as well as its commercial viscosity. The *absolute viscosity* which takes both of these into account, usually appears in the answers to problems in bearing design and lubrication. Absolute viscosity may be expressed in poises in the metric system or Reyns in the English system. See p. 13–44. See notes A and B on Fig. 107, for methods of conversion from one system to the other. Specific gravities used in such conversions must be those of the temperature under consideration, and be expressed in relation to water at 39.1° F. Specific gravities of oils decrease with temperature. At 100° F., 0.865 represents an average value for paraffin-base oils, and 0.915 an average value for naphthene-base oils. Hence the absolute viscosity of two such oils, whose Saybolt viscosities are the same at 100° F., will vary in the ratio of 0.865/0.915. It is possible, however, to find a different temperature at which the absolute viscosities of these two oils are identical, and *vice versa*. That is, oils identical as to viscosity and temperature in the usual commercial units will be identical in absolute viscosity units at some other temperature. Fig. 108 affords a means of working intelligently from one system to the other for mineral oils. The chart is so constructed as to permit oil to be specified in commercial units in order to obtain the desired oil with the absolute viscosity assumed, and at the same time not be concerned as to whether the oil is of one base or the other. The principles underlying this chart are explained in Howarth, Current Practice in Pressure Speeds, Clearances and Lubrication of Oil Film Bearings (20).

Example 3.—Find a Saybolt specification that may be used to obtain mineral oils whose absolute viscosities are the same, 0.24 poise ($3.4 \times 10^{-6}$ Reyns), at 120° F. *Procedure:* In Fig. 108, draw line $AB$ through the value 0.24 on the metric scale, intersecting at $L$ the ordinate of 120° F. (lower scale). Reading on the two curved scales, $L$ represents a temperature of 104° F. and a commercial viscosity of 183 sec. S.U.V. From the scales at the bottom of the chart, 183 sec. S.U.V. corresponds to 5.4 Engler degrees and 158 sec. Redwood viscosimeter.

# ROLLING CONTACT BEARINGS

## BALL BEARINGS

**By J. S. Tawresey**

In rolling contact or anti-friction bearings the load is supported on a series of rolling elements and rolling friction is substituted for the sliding friction of the plain bearing. Ball bearings support the load on a series of balls, and roller bearings carry the load on rollers having various shapes, according to the particular design of bearing. Ball bearings often are referred to as having point contact between balls and raceways; in the same sense, roller bearings are said to have line contact between rollers and races. These are merely descriptive terms, since the elastic deformation occurring under load results in substantial areas of contact in either type.

The comparative utility of ball and roller bearings is summarized on a qualitative basis, and from the point of view of application as follows:

| | *Ball Bearings* | *Roller Bearings* |
|---|---|---|
| Range of size | Small and medium | Medium and large |
| " " load | Normal and heavy | Heavy and extra heavy |
| " " speed | High and medium | Medium and low |
| Type of service | Normal duty<br>Normal shock | Heavy duty<br>Heavy shock |
| Frictional torque | Lowest | Somewhat higher |

Compared with plain bearings, both ball and roller bearings can sustain heavy overloads for short periods without failure. Their lubrication requirements are moderate; this is especially true for high-speed operation. Starting friction of ball and roller bearings is but slightly greater than running friction, an outstanding advantage in machinery that is required to start frequently under load. Anti-friction bearings are manufactured and applied as interchangeable units, thus greatly simplifying the problem of service replacement when occasion arises.

Ball bearings are available for virtually all types of modern machinery. The primary consideration in their use is the factor of reliability in service, and operation not subject to critical limitations which affect the performance of plain bearings. Ordinarily the failure of a ball bearing is characterized by a relatively long period of gradual impairment of smoothness, affording ample opportunity for detection. Contrasting with this, the plain bearing is disposed to develop an accelerated type of failure, resulting in acute conditions of seizure and shut-down.

### 1. BALL BEARING STANDARDS

Dimensional and tolerance standards have been adopted for various series and sizes of ball bearings. These are listed in the S.A.E. Handbook of standards and recommended practice. The general acceptance of these standards by both manufacturer and user of bearings gives assurance of their commercial availability. See Tables 1 to 7 for a listing of the most important types and series of single-row and double-row bearings. Dimensions are based on the metric system as a result of bearings first having been manufactured in Europe. Standard tolerances on the bore of the inner race and outside diameter of the outer race are listed in connection with shaft and housing fits, page 13–75.

The manufacture of standard bearings in mass production definitely discourages the use of special and individual designs in which the cost is out of all proportion to that of standard product. In this respect, practice in the use of anti-friction bearings is in marked contrast with that of plain bearings which frequently are designed to meet a specific condition.

### 2. BALL BEARING TYPES

Bearing types are classified readily on the basis of their design and constructional features, leading naturally to a consideration of their functional purpose in terms of load and speed.

**ANNULAR BALL BEARINGS** consist essentially of an inner race, an outer race and a complement of balls spaced by a suitable cage or retainer. They are made in both the single-row, Fig. 1, and double-row, Fig. 6, construction, and may have either a radial contact between balls and raceways, or an inclined angular contact. Radial-contact bearings primarily are intended for radial load, but generally provide for axial stability in both directions where a moderate axial displacement is permissible. Single-row angular-contact bearings, Fig. 7, have a substantial thrust capacity and provide rigid axial support in one direction only. The double-row angular-contact construction has substantial thrust and combined load capacity, together with rigid axial support in both directions. The speed limit of double-row bearings generally is restricted more than that of the single-row, because of features affecting the construction and balance of the cage. The double-row type also is more rigid and sensitive to misalignment than is the single-row.

Types of Ball Bearings

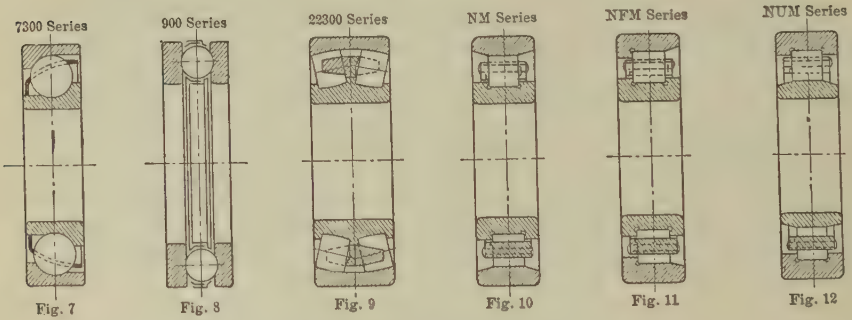

FIG. 7. Angular Contact Type
FIG. 8. Thrust Bearing
FIG. 9. Spherical Roller Bearing
FIGS. 10–12. Cylindrical Roller Bearings
Types of Ball and Roller Bearings

**SELF-ALIGNING RADIAL** bearings, Fig. 3, have a spherical surface to provide for misalignment between inner and outer races. Because of the comparatively small contact angle between balls and raceways, they are primarily radial load carriers and have only sufficient thrust capacity for stabilizing under incidental axial loads. Such bearings made to the wide type standard, Fig. 5, have a substantial thrust capacity due to the greater contact angle. The self-aligning construction has a unique advantage in the case of radial loads which rotate with the shaft, such as those due to mechanical unbalance. Under these circumstances the load is localized on the grooved raceways of the inner ring where the capacity is greater than that provided by the ball complement of the single-row grooved-type bearing. Self-aligning bearings having a single row of balls, and those employing a spherical shell enclosing the outer race manifestly are limited in usefulness and generally inferior to the conventional design.

**THRUST BEARINGS** of the so-called flat type, Fig. 8, have a contact angle of 90 deg., or a load line between ball and raceways that is parallel with the axis of the shaft. The small-bore washer is secured to the shaft, and the large-bore washer is supported by the housing. This type is essentially a one-direction thrust carrier. Thrust in both directions necessitates the use of duplicate units or a bearing of the double direction type. On a horizontal shaft, the weight of the retainer and balls tends to radial displacement of the balls and causes wedging in the grooves. This tendency is opposed by thrust load on the bearing and may be corrected by provision of an adequate pre-load. Thrust bearings are made both with flat rings and spherically-seated rings to allow alignment. In the aligning type, frictional resistance and difficulty of properly centering, makes the spherical seat less attractive in practice than it appears when considered simply as a design feature.

The important characteristics and features of the various ball bearing types can be generally summarized as follows:

**Single Row Radial** (Fig. 1)

Sizes up to 300 mm. bore.
Normal load, combined radial and thrust.
High speed.
Axial displacement permissible under reversing thrust.

**Self-aligning** (Fig. 3)
**Single Row Width**

Predominating radial load, limited thrust capacity.
High speed.
Self-aligning.

**Angular Contact** (Fig. 7)
**Single**

Predominating thrust load, in one direction.
High speed.
Close control of axial displacement.

**Single Direction Thrust** (Fig. 8)

Thrust load only, in one direction.
Limited speed.
Minimum axial displacement.

**Double Row Radial** (Fig. 6)

Sizes up to 110 mm. bore.
Heavy loads, combined radial and thrust.
Medium speed.
Close control of axial position under reversing thrust.

**Self Aligning** (Fig. 5)
**Wide Type**

Predominating radial load, substantial thrust capacity.
High speed.
Self-aligning.

**Angular Contact**
**Duplex**

Predominating thrust load, reversing direction.
High speed.
Close control of axial displacement.

**Double Direction Thrust**

Thrust load only, reversing.
Limited speed.
Minimum axial displacement.

**DIMENSIONAL AND CAPACITY TABLES.**—Tables 1 to 7 show the sizes and load-carrying capacities of the various types of ball bearings. They are compiled from tables issued by S.K.F. Industries, Inc., certain of the larger sizes being omitted. The dimensions, however, agree with the established standards of the S.A.E., and of other manufacturers.

**LOAD CARRYING CAPACITY.**—The ability of a ball bearing to carry shock load and absorb impact depends on the relation between deformation and stress which exists at the load contacts. The capacity of any bearing for sustaining such loads can be judged by the volume of material subjected to stress. It is important to observe that this property is not directly proportional to the normal load rating. For shock loads, the medium and heavy series bearings are far superior to the light series, in sizes having equivalent load ratings.

**MODIFICATION OF BASIC TYPES.**—There are numerous modifications of the basic bearing types, and supplementary provisions have been added to adapt them to certain specialized uses. Among these are the tapered bore adapter sleeve mounting, Fig. 4, the extended inner race set-screw and lock mounting, the plate type shield, the felt washer seal, the outer race snap ring mounting, Fig. 2, and the double seal self-lubricated type. Such specialized types require detailed consideration in order to assure their effective use in any particular design. Aside from an appreciation of elementary principles, experience serves as the best guide in the successful application of bearings to any particular machine. To assist in this respect, the principal bearing manufacturers offer technical advice to prospective users of their product. It is sound policy for engineers and designers to avail themselves of such service.

## 3. DESIGN PRACTICE

**FACTORS GOVERNING SELECTION.**—The type of bearing should be chosen with due regard to the character of load, speed limitation and the need for radial and axial rigidity. The size selected should establish an economic balance between load capacity and service requirements for life of the machine. In many instances, dimensional restrictions affecting shaft size, outside diameter, or width of bearing are controlling factors in

(*Continued from* p. 13–61)

deciding the bearing size. Ordinarily a rather wide range of bearing sizes is available to meet given conditions of load and speed; in such cases it is wise to determine which types and sizes show an advantage in the matter of cost.

Primary importance attaches to the proportioning of the bearing to the average load. Unlike practice with plain bearings, it is not desirable to base design on maximum or extreme conditions. The service life of an anti-friction bearing ultimately is determined by the *mean effective*, rather than the maximum, load, and a large reserve capacity is available for overload of short duration. The attention of the designer should be directed to making a good estimate of the average load conditions, and from such data bearing life may be estimated with a comparable degree of accuracy.

**LOAD-LIFE RATING.**—The load-life rating of ball bearings has been developed empirically from extensive series of tests, in which the lives of very many bearings were observed when operated under known and controlled conditions. This investigation disclosed the fact that ball bearings ultimately show a typical fatigue deterioration of the raceway surfaces. The repetition of contact stresses between raceways and the loaded balls induces a progressive system of surface cracks, and continued operation results in flaking or spalling of the surface. The rough and eroded appearance of the surfaces is characteristic of this action. Fatigue constitutes an inherent limitation to normal useful life of a bearing and an understanding of the factors involved affords the basis on which bearing life is predetermined.

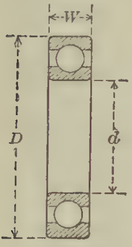

Fig. 13

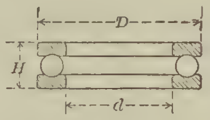

Fig. 14

In considering the life of a bearing it should be noted that faulty design practice may lead to premature failure as the result of intrusion of dirt, water or other destructive foreign material. Neglect of lubricant supply, and other forms of abuse, may unnecessarily impair bearing life. These conditions may be avoided or corrected by the exercise of proper judgment in design and suitable control in maintenance. When a bearing is selected, of type and size adapted to the operating conditions, and due consideration is given to the details of mounting design and installation, the service performance can be accurately forecast by means of the life-load rating.

A group of bearings identical in design and manufacture and tested under the same conditions are found to show a characteristic deviation among the individual lives. This dispersion is common to many types of endurance phenomena, including such diverse entities as human mortality, and lives of electric lamps, gear teeth and valve springs. The average life of the whole group tested serves as the best description of the endurance quality of the group, but in addition, it is important to define the sequence of failure, especially that of the shortest lives in relation to the group average. Extensive tests have shown that 90% of the bearings attain a life exceeding one-fifth of the average life, or that 10% of the bearings may develop fatigue at a life less than one-fifth of the average. Experience in the engineering and practical application of ball bearings has shown that the life exceeded by 90% of the bearings is a useful criterion of reliability, while the average life of the group serves as a direct measure of productive performance. This conception of bearing life employs a statistical viewpoint, wherein the individual bearing loses its identity and estimates of life refer to a group as a whole.

**Endurance-Load Relations.**—The endurance properties of materials are conventionally investigated on the basis of the *S–N* diagram wherein the intensity of stress *S* is related to the number of stress cycles *N*. Sufficient data will serve to indicate the existence

* Thrust bearings have not been conclusively standardized (1937). This table gives the standards of S.K.F. Industries, Inc. † See Fig. 14.

‡ *R* = radius of maximum fillet on shaft or housing that will be cleared by bearing.

of any fatigue limit, or that stress below which progressive failure will not occur. Endurance properties of bearings have been investigated in the same manner, but it is found more convenient to deal with the external load applied to the bearing, and the total number of revolutions attained prior to the appearance of fatigue, as the related variables. A given point on the raceway is subjected to a cycle of stress each time that it comes into contact with a ball in the loaded zone. The fundamental relation between life and load is that the total number of revolutions, before the inception of fatigue, will vary inversely as the cube of the applied load. This basic relation is independent of the speed at which

* See Fig. 13.

† *R* = radius of maximum fillet on shaft or housing that will be cleared by bearing.

intensity will result in extremely long life, but fatigue ultimately will develop and progressively become more apparent.

The ball bearing industry has made an important contribution to the art of machine design in that bearing life is recognized as a statistically determinant quantity, and fatigue is reckoned with as a predetermined factor subject to definite laws.

## 4. SELECTION OF BEARING SIZE

Selection of the proper bearing size is effected by equating a measure of the operating conditions to a corresponding measure of the bearing performance. Operating conditions are defined in terms of the bearing *load* and shaft *speed.* Performance is expressed in terms of the *reference rating* and the *design life.* The equation between the two requirements is:

$$P \times \sqrt[3]{N} = R \times (1/\sqrt[3]{H}) \times 100 \quad . \; . \; . \; . \; . \; . \; . \; . \quad [1]$$

where $P$ = load, lb.; $N$ = speed, r.p.m.; $R$ = reference rating, lb.; $H$ = design life, hours. It will be observed that this affords a direct solution of the problem of selecting bearing size, expressed in terms of the quantities that are naturally involved. This design practice supersedes former methods which employed ambiguous factors in an effort to define standards of performance.

Reference rating values for various types of bearings are given in the Tables 1 to 7, arranged according to series and size. The basis for the reference rating is explained in detail on p. 13–72.

When bearing load $P$ and speed $N$ are given, corresponding values of reference rating and design life are found as follows:

**Reference Rating** $R$ required for a design life $H$ is

$$R = P \times \sqrt[3]{N} \times (\sqrt[3]{H}/100) \quad . \; . \; . \; . \; . \; . \; . \quad [2]$$

**Design Life** $H$ obtained with a given reference rating $R$ is

$$H = \{1/(P^3 \times N)\} \times R^3 \times 1{,}000{,}000 \quad . \; . \; . \; . \; . \; . \; . \quad [3]$$

With given values of reference rating $R$ and design life $H$, permissible load or speed is found.

**Load** $P$ which can be carried at a given speed $N$ is

$$P = (R/\sqrt[3]{H}) \times (100/\sqrt[3]{N}) \quad . \; . \; . \; . \; . \; . \; . \; . \; . \quad [4]$$

**Speed** $N$ permissible for a given load $P$ (speed not to exceed limit of r.p.m. for given bearing) is

$$N = (R^3/H) \times (1{,}000{,}000/P^3) \quad . \; . \; . \; . \; . \; . \; . \; . \quad [5]$$

**BEARING SELECTION CHART.**—A graphical solution of these relations is given by the chart, Fig. 15, which will be found sufficiently precise for preliminary design and checking purposes. In using the chart it is important to note that corresponding values of *load* and *speed*, and corresponding values of *reference rating* and *design life*, must be taken together in entering or reading from the diagram.

Design life and its relation to average service life for a group of bearings is discussed on p. 13–74.

**Use of the Chart.**—The chart can be used for the selection of bearing size. For this purpose, corresponding values of load and speed are located on the $P$ and $N$ scales, from which the chart is entered to locate the diagonal guide line through their intersection. This guide line then defines corresponding values of reference rating and design life under the given conditions of load and speed. The reference rating is the key to the bearing size in using the diagram.

When the chart is employed to determine permissible load or speed, it is entered from corresponding values of reference rating and design life located on the $R$ and $H$ scales. The intersection of these given values locates the diagonal guide line which will define the permissible combinations of load and speed, as read from the $P$ and $N$ scales.

### Load

The load used for design purposes is based on an analysis of the reactions affecting the bearing, and is reduced to an estimate of the average radial component and thrust components. Factors of safety should not be included in such calculations, as this defeats the purpose of determining the design life and corresponding average service life.

Combined thrust and radial load is converted to an equivalent radial load by:

$$P = P_R + Y \times A \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \; . \quad [6]$$

where $P$ = equivalent radial load, lb.; $P_R$ = radial load component, lb.; $A$ = thrust or axial load component, lb.; $Y$ = factor, converting thrust to radial load, and depending on type and size of bearing. Values of the $Y$ factor are as follows for various types of bearings:

**Single-row Deep-groove Bearings.**—For high speed, $Y = 1.5$. For low speed, $Y = 1.0$.

**Double-row Angular-contact Bearings.**— $Y = 1.1$.

**Self-aligning Ball Bearings.**—Medium series 1300 to 1303, $Y = 2.5$; 1304 to 1306, $Y = 3.0$; 1307 to 1324, $Y = 3.5$. Light series, wide type, 2200 to 2206, $Y = 2.0$; 2207 to 2209, $Y = 2.5$; 2210 to 2222, $Y = 3.0$. Medium series, wide type 2300 to 2304, $Y = 1.5$; 2305 to 2372, $Y = 2.0$.

**Spherical Roller Bearings.**—22216 to 22264, $Y = 3.0$; 22308 to 22356, $Y = 2.0$.

**AVERAGE LOAD.**—When a bearing is subjected to a varying load, this can be reduced to an equivalent *mean effective load* by an averaging procedure. For this purpose the varying operating conditions should be expressed in terms of load and speed, and the corresponding percentage of time, or of the total life, during which they apply. Using subscripts to designate the several operating conditions, the mean effective load and corresponding average speed is determined as follows:

$$N_\epsilon = \Sigma\, N_1\phi_1 + N_2\phi_2 + N_3\phi_3 + \ldots N_n\phi_n \quad [7]$$

$$P_\epsilon = \sqrt[3]{\frac{1}{N_\epsilon}\Sigma\, P_1{}^3N_1\phi_1 + P_2{}^3N_2\phi_2 + P_3{}^3N_3\phi_3 + \ldots P_n{}^3N_n\phi_n} \quad [8]$$

where $N_\epsilon$ = effective or average speed, r.p.m.; $P_\epsilon$ = effective or average load, lb.; $P$ = load, lb.; $N$ = speed, r.p.m.; $\phi$ = percent of time expressed as a decimal; subscripts 1, 2, 3 . . . $n$ indicate the several given operating conditions.

Values of $P_\epsilon$ and $N_\epsilon$, determined as above, can be used in the selection of bearing size with the assurance that the design life and average service life, so estimated, will be exactly the same as that due to the varying load conditions.

The chart, Fig. 15, can be used to obtain a graphical solution of the selection of bearing size for a varying load. In this case the auxiliary scales, at the bottom and to the left, marked "scale of $(R)^3$" and "percentage of time" are used. The chart is entered with corresponding values of load and speed for one of the operating conditions, which locates a diagonal guide line. The chart then is entered with the given percentage of time and from the intersection with the same diagonal, the corresponding value of $(R)^3$ is determined. The value of $(R)^3$ is found in this way for each of the operating conditions and the sum of these values determined. The chart is then entered with this sum on the $(R)^3$ scale and the 100% ordinate from the "percent of time" scale, fixing the location of a final diagonal guide line. This diagonal defines corresponding values of reference rating and design life, corresponding exactly with the varying load condition as originally defined.

Care should be taken in noting the position of the decimal point in reading from the $(R)^3$ scale, and in checking the individual values for percent of time, to add up to 100%.

## Speed

The life-load relation does not apply for speeds under 15 r.p.m. The maximum speed at which a bearing may be operated depends on the type and size, and especially on the material and construction of the cage or retainer. It will be considerably influenced by the provision made for lubrication. A speed limit line is shown on the chart, Fig. 15. This may be taken as applying directly to single-row ball bearings. For other bearing types, it is advisable to consult with the bearing manufacturer when speeds are high, as suggested by proximity to the limit line of the chart.

When the speed varies, an average value as determined by equation [7] should be employed for design purposes.

The maximum static load which may be applied to a bearing can be approximately determined by taking the speed $N$ as 15 r.p.m. and the design life $H$ as 500 hr.

## 5. REFERENCE RATING

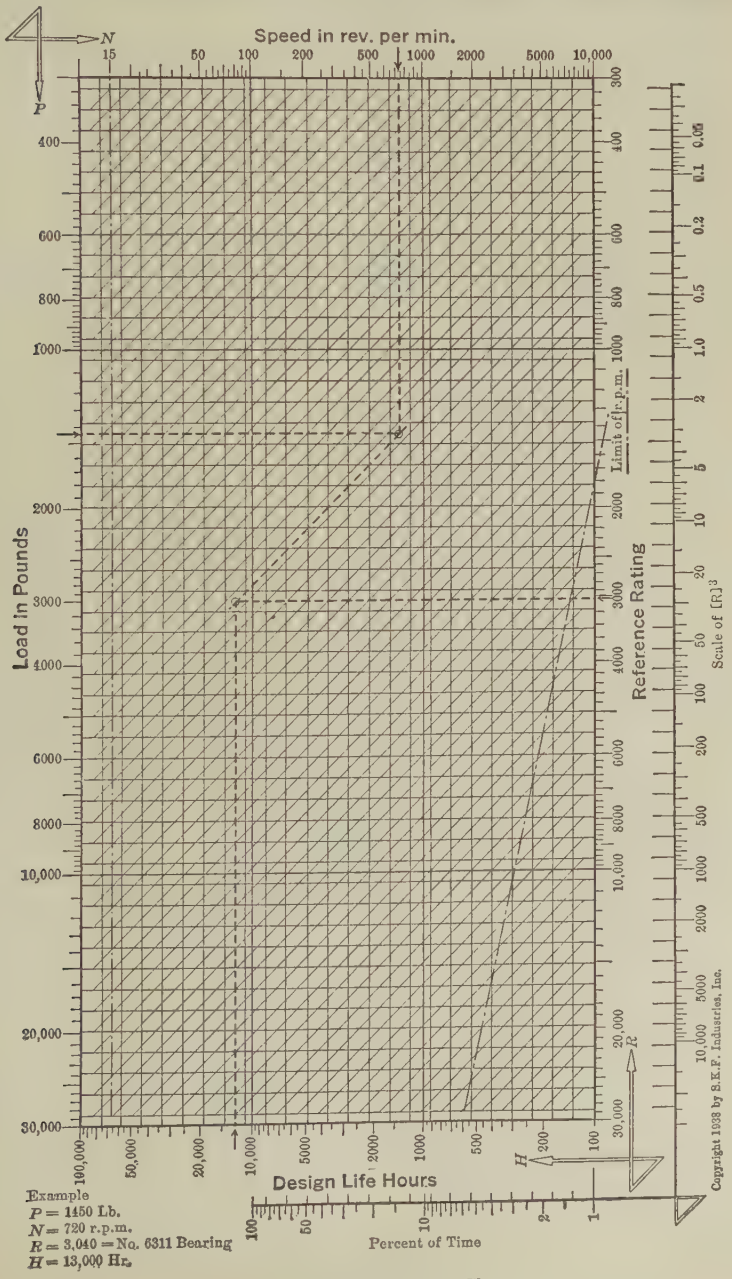
**REFERENCE RATING** is the load in pounds, which applied to the bearing at a speed of 1000, r.p.m., will result in a design life of 1000 hr., or an average service life of 5000 hr.

The actual load carrying capacity of various types of anti-friction bearings cannot be inferred by the indiscriminate comparison of catalog ratings. There is a conspicuous lack of uniformity in the rating practice followed by different manufacturers in published references to their product. It is essential that a uniform basis be established to enable a true comparison to be made of the load-carrying ability of various types, series and sizes of bearings. The reference rating employed herein has been developed for that purpose.

The reference rating serves as a measure of the specific load carrying capacity of a given bearing. It can be calculated from a knowledge of the design features and an empirical constant determined for each particular type of bearing. The general equation for ball bearings is:

$$R = C \times Z^{2/3} \times \{D^2/(1 + 0.508D)\} \cos \alpha \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [9]$$

where $R$ = reference rating, lb.; $C$ = an empirical constant dependent on design and



Example
$P$ = 1450 Lb.
$N$ = 720 r.p.m.
$R$ = 3,040 = No. 6311 Bearing
$H$ = 13,000 Hr.

FIG. 15. Bearing Selection Chart

material, and established by endurance tests; $Z$ = number of balls per row; $D$ = diameter of ball, in.; $\alpha$ = contact angle, measured from a plane normal to the shaft axis.

For single-row deep-groove bearings, Table 1, and self-aligning ball bearings, Table 2, this equation becomes:

$$R = 1630\,Z^{2/3}\{D^2/(1 + 0.508\,D)\}\cos\alpha \quad [10]$$

For double-row angular-contact bearings, Table 3,

$$R = 2900\,Z^{2/3}\{D^2/(1 + 0.508\,D)\}\cos\alpha \quad [11]$$

For single-row angular-contact bearings, rated in thrust load, Table 4,

$$R = 4200\,Z^{2/3}\{D^2/(1 + 0.508\,D)\}\sin\alpha \quad [12]$$

Thrust type bearings, Table 5, are rated in thrust load, and

$$R = 2175\,Z^{2/3}\{D^2/(1 + 0.508\,D)\} \quad [13]$$

The reference rating is stated in terms of radial load for radial bearings, and thrust load for single-row angular-contact and thrust-type bearings. The rating applies to the normal condition of stationary housing and rotating shaft, in which the radial load is distributed over the inner race and localized on the outer race. Under the reverse condition, where the load is distributed around the outer race and localized on the inner race, the reference rating must be multiplied by a correction factor as follows: Self-aligning ball-bearing, correction factor = 0.90; other types of radial bearing, correction factor = 0.75.

The reference rating is the key value serving to relate a particular bearing size to the problem of load, speed and design life.

## 6. DESIGN LIFE AND SERVICE LIFE

**DESIGN LIFE** is a measure of bearing performance that is particularly useful in design practice. It is the number of hours for which at least 90% of a group of bearings will operate before the inception of fatigue. Practical experience has proven this proportion to be a valuable guide in estimating the reliability of a given design.

**SERVICE LIFE** is the average number of hours for which the entire group of bearings will operate prior to the inception of fatigue. It is equal to five times the number of hours comprising the design life. The service life is an average value representing the economical performance of a group of bearings and serving as a criterion of bearing replacement.

### Examples of Bearing Selection

Example 1.—Blower equipment is to be installed in a power substation where continuous operation is contemplated and a high degree of reliability is essential because of cost and inconvenience of a shut-down. Past experience has shown an average service life of 8 years to be a satisfactory basis for proportioning the bearings in such equipment.

*Operating conditions* are: $P_R$ = radial load on bearing = 950 lb.; $A$ = thrust load on bearing = 400 lb.

The equivalent radial load is determined by applying the appropriate $Y$ factor (see p. 13–71). Because of the substantial thrust component it is decided to use the deep-groove type of bearing. The $Y$ factor is taken as 1.25, intermediate between the values for low and high speed. Then:

$P$ = equivalent radial load = 950 + (1.25 × 400) = 1450 lb.; $N$ = given speed = 720 r.p.m.

*Performance Requirements.*—The designated average service life of 8 years, for continuous operation, is expressed in hours = 8 × 365 × 24 = 72,080 hr.

Design life $H$, to be used for the bearing selection, is 1/5 of the average service life, whence $H$ = 72,080/5 = 14,420 hr. The reference rating $R$, required under these conditions, is then found from equation [2], from which

$$R = 1450 \times \sqrt[3]{720} \times (\sqrt[3]{14{,}420}/100) = 3171 \text{ lb.}$$

Referring to the ratings for single row groove type bearings, Table 1, it is seen that the conditions are met by the following bearings:

| Bearing No. | Bore, in. | Outside Diam., in. | Width, in. | Reference Rating |
|---|---|---|---|---|
| 6216 | 3.1496 | 5.5118 | 1.0236 | 3100 |
| 6311 | 2.1654 | 4.7244 | 1.1417 | 3040 |
| 6409 | 1.7717 | 4.7244 | 1.1417 | 3370 |

The final selection of bearing size then depends on shaft size and outside diameter requirements, imposed by the design.

Example 2.—A double-row groove-type of bearing with a bore of about 2 in. is to support a radial load, rotating with the shaft. Speed $N$ is 720 r.p.m. Design life $H$ is established at 14,000 hr. in consideration of the particular service requirements of the equipment. Required the permissible radial load for the bearing size selected.

A No. 5310 bearing (see Table 3) has a bore of 1.9685 in. and a reference rating of 4280 lb. The correction factor to account for the rotating character of load (see above) is 0.75. Therefore, the rating to be used is $R$ = 4280 × 0.75 = 3210.

The permissible load is found by equation [4], whence

$$P = (3210/\sqrt[3]{14{,}000}) \times (100/\sqrt[3]{720}) = 1486 \text{ lb.}$$

Example 3.—A No. 6312 single-row groove-type bearing is subjected to a variable load cycle, as follows, expressed in load, speed, and percent of time:

| | | | |
|---|---|---|---|
| $P_1 = 2000$ lb. | $P_2 = 1000$ lb. | $P_3 = 500$ lb. | $P_4 = 0$ |
| $N_1 = 1000$ r.p.m. | $N_2 = 2000$ r.p.m. | $N_3 = 3000$ r.p.m. | $N_4 = 0$ |
| $\phi = 25\%$ | $\phi_2 = 50\%$ | $\phi_3 = 10\%$ | $\phi_4 = 15\%$ |

The average load conditions equivalent to this cycle are determined by equations [7] and [8]. From equation [7],

$$N_\epsilon = (1000 \times 0.25) + (2000 \times 0.50) + (3000 \times 0.10) = 1550 \text{ r.p.m.}$$

From equation [8],

$$P_\epsilon = \sqrt[3]{(1/1550)\{2000^3 \times 1000 \times 0.25) + (1000^3 \times 2000 \times 0.50) + (500^3 \times 3000 \times 0.10)} = 1251 \text{ lb.}$$

The design life of the No. 6312 bearing under this variable load cycle then is determined by substituting in equation [3], taking the values of $P_\epsilon$ and $N_\epsilon$ as the values of $P$ and $N$ in the equation. From Table [1], $R = 3480$. Then

$$H = \{1/(1251^3 \times 1550)\} \times 3480^3 \times 1{,}000{,}000 = 13{,}900 \text{ hr.}$$

$$13{,}900 \times 5 = 69{,}500 \text{ hr.} = \text{average service life.}$$

This same problem is solved by using the chart, Fig. 15. Entering the chart with load 2,000 and speed 1,000, the $R^3$ value for 25% of the time is noted as 20. Corresponding values for loads and speeds at 50% and 10% of the time are 9.5 and 0.35, respectively. The sum of these $R^3$ values is 29.85.

Entering the chart from the $R^3$ scale at 29.85 and 100% on the percent of time scale determines the final guide diagonal giving corresponding values of rating and life. For a reference rating of 3480 lb. (No. 6312 bearing) the design life is read as 14,000 hr.

Example 4.—A spherical roller bearing, size 22332, is to be used to support a shaft rotating at 500 r.p.m. It is desired to determine the load that may be applied for an average service life of five years, operating 4,000 hr. per year.

The average service life in hours is equal to 5 × 4,000 = 20,000 hr. Design life $H = 20{,}000/5 = 4{,}000$ hr.

The permissible load is found from equation [4], the reference rating for bearing No. 22332 being (Table 6) 59,800 lb.

$$P = (59{,}800/\sqrt[3]{4000}) \times (100/\sqrt[3]{500}) = 47{,}500 \text{ lb.}$$

Using the chart, the reference rating 59,800 is divided by 10 to give 5,980 and the load corresponding to speed 500 r.p.m. is read as 4,800. The load then is multiplied by 10 to give 48,000 lb. This procedure is equivalent to moving the decimal point simultaneously on the scale of reference rating and on the scale of load.

## 7. PRACTICE IN MOUNTING BALL BEARINGS

**TOLERANCES.**—Ball bearings are manufactured to close tolerances on both internal and external dimensions. The degree of accuracy observed is in no sense an elaborate or unnecessary refinement. A ball bearing is essentially a statically indeterminant structure in which the externally applied load is internally reacted by a series of individual ball contacts. Under these circumstances, the magnitude of the several ball reactions is determined by the combined clearances and deformations existing at the contacts. Uniformity in this respect can be obtained only when a high degree of accuracy is observed in the manufacture of all component parts. This will insure a proper distribution of the load among the balls, and smooth running will result if corresponding care is exercised in the mounting of the bearing.

The unit of measurement and tolerance generally used in the manufacture of bearings is 0.0001 in. Precision of external dimension is necessary to allow accurate fitting and the requisite interchangeability when a bearing is installed. This implies a comparable precision in the tolerances for shaft seat diameter and housing bore. Both inner and outer ring will, through elastic deformation, tend to assume the size and shape of the mating machine part. This tendency is more pronounced in the case of interference or press fits. Inner races will expand measurably to take up the initial internal clearance of the bearing, and outer races will contract with a similar effect, that may be exaggerated when the housing bore is out of round. The combination of shaft and housing fit should be selected with due regard for assembly and disassembly requirements and a consideration of their effect on the internal clearance of the bearing.

**FITS.**—A general principle to be observed in the mounting of ball bearings is the use of an interference or press fit for securing the ring, either inner or outer, which rotates with respect to the direction of the radial load. This is necessitated by the tendency of that ring to progressively creep on its support and to develop wear that is aggravated by a peening effect. Frictional constraint, resulting from a press fit of the ring, is the most effective means of preventing this action, although suitable types of lock-nut and washer are useful as a supplementary provision. The tendency to creep is greater under heavy load and shock, and under these conditions relatively heavier fits should be used. With moderate loads, in the absence of vibration and shock, lighter fits are sufficient, especially when supplemented by a lock-nut. Formerly it was believed that some advantage would accrue by allowing the race that is stationary with respect to the radial load, to have a so-called creeping fit. This view is now discredited by an understanding of the principles affecting fatigue deterioration of the bearing, and practical difficulties encountered in preventing a creeping ring from spinning in the presence of an unbalanced load component.

Insufficient clearance or a tight internal fit generally is conducive to heating of the bearing in operation, and to rough running. The heavier classes of shaft fit will result in normally fitted bearings being internally tight after mounting. However, when a bearing is subjected to heavy load, the accompanying deflection at the load-carrying contacts will serve to relieve the effect of initial tightness. This principle is involved in the action of the so-called preloaded type of bearing, which is particularly useful in meeting exacting requirements of precision, and in minimizing displacement of the bearing under load. With bearings selected for application to precision machinery, it is desirable to employ light press fits in order to avoid disturbing the initial internal fit of the bearing.

The procedure to be followed in assembly and disassembly of the machine parts must be considered in deciding upon the shaft and housing fits to be used. Ordinarily but one bearing on a given shaft should be located axially and all other bearings on the same shaft should have endwise float permitting axial adjustment under thrust load and temperature gradient. The race, either inner or outer, which provides the float naturally must not be the one for which a press fit is required in consideration of the radial load.

To properly meet the various requirements encountered in practice, it is necessary to employ a number of different classes of shaft and housing fit, adapted to the tolerances and the internal fit of bearings. This classification should provide a graduated sequence of fits, adjusted to give a uniform variation, and permitting machining and grinding tolerances suited to design and manufacturing requirements. Such a schedule developed specifically for use with ball and roller bearings is given in Table 8 for shaft fits, and Table 9 for housing fits. Table 10 is a metric conversion table for bearing bores and outside diameters.

**General Requirements.**—Radial loads acting in a fixed direction, require an interference or press fit between shaft and inner race when the shaft rotates, and between the housing and outer race when the housing rotates.

* *Rotating Housing* refers to a loading condition in which the outer race rotates with respect to the direction of the load. † *Rotating Shaft* refers to a loading condition in which the inner race rotates with respect to the direction of the load.

Radial loads not fixed in direction, but rotating with a moving part, reverse the requirements. An interference fit is used with the outer race for a rotating shaft, and for the inner race with a rotating housing.

A radial load that is the resultant of two components, one fixed in direction and one rotating, requires a compromise in the selection of fits. This should favor the predominating component.

Rotating loads are induced by mechanical unbalance or may result directly from the interaction of machine forces.

The numerical designation used for describing the fit is the mean value of the clearance or interference, measured in units of 0.0001 in.

The quantitative character of any particular class of fit is best judged from an estimate of its average value. The frequency distribution of production parts, both bearings and machine elements, follow characteristic patterns. A negligible percentage of pieces is

found at either limit of the working tolerance and a comparatively large percentage lies close to the mean or average value. The result of random assembly will be a large percentage of fits close to the mean, with an inconsequential number approaching either extreme value. Accordingly it is erroneous practice to attempt to define a fit by the maximum and minimum values which seldom, if ever, occur. It is desirable to designate a class of fit by some appropriate symbol, and to employ this in specifying the use. An effective comparison of one class of fit with another is made by referring to their mean or average values. A further statistical check will enable a frequency allotment to be made showing the percentage of assemblies having a fit within given limits about the mean. Experience in the application of ball bearings has shown that approximately 95% of the assemblies lie within a range of about one-half that between the extreme limits of the fit.

## 8. LUBRICATION OF BALL BEARINGS

**BASIC REQUIREMENTS** for lubrication of ball bearings include provision for the sliding contact between balls and retainer and the protection of the highly finished surfaces from corrosion. The supporting surfaces of the retainer are essentially plain bearings and must be lubricated as such by a lubricant film. The surface of the balls and raceways is particularly subject to corrosion, which will accelerate fatigue action and result in abrasive wear of the bearing parts.

A comparatively small quantity of lubricant, either oil or grease, will suffice for the requirements of the bearing if it is consistently present and properly distributed to the bearing surfaces. An excess quantity of lubricant is undesirable, and will cause the bearing to run at high temperature and aggravate leakage from the housing.

**OPERATING TEMPERATURE** of a bearing is a controlling factor in selecting the proper grade of lubricant. Load, speed and surrounding conditions directly affect this temperature, as does also the particular type of bearing and the design of the shaft enclosures. The viscosity of an oil and the type and consistency of a grease should be adapted to the operating temperature. Under normal conditions ball bearings will run at a temperature from 10° F. to 60° F. above surroundings.

**TYPE OF LUBRICANT.**—Either grease or oil is successfully used for the lubrication of ball bearings over a wide range of speed and operating conditions. The use of grease simplifies the design from the point of view of shaft enclosures to prevent leakage, but requires care in application to assure the grease gaining access to the bearing and at the same time to prevent overloading. Oil lubrication allows the use of a suitable oil level indicator as a check on the quantity in the housing. Oil generally is to be preferred for speeds above 10,000 r.p.m., and for operating temperatures, above 200° F.

**CONSUMPTION OF OIL OR GREASE** in a ball bearing is relatively small, but proper provision should be made in the housing design for its periodic renewal. Aside from the loss of lubricant, due to evaporation and leakage, both oil and grease are subject to progressive deterioration over a period of time. Contamination of the lubricant is the cumulative result of dirt, moisture or other foreign material gaining access to the housing. Wherever possible, the old lubricant should be removed and the bearing washed out with clean, hot oil, before renewal of the lubricant. In general, the lubricant can be applied and the housing sealed without subsequent attention for a period ranging from six months to two years, according to the severity of operating conditions. The necessity for renewal can best be determined, in the absence of definite information, by periodic inspection during the first year or more of service.

**SPECIFICATIONS** of physical and chemical properties cannot in themselves adequately define the qualities of a lubricant. Materials and methods used in refining and manufacture have an important influence on the performance of the lubricant in service. Many reputable manufacturers have specialized in the development of lubricants suitable for use with ball bearings, and this applies particularly to greases. In consideration of the fact that anti-friction bearings are susceptible to abrasive and corrosive action, only high-grade products should be used for their lubrication, and these should be obtained from established sources prepared to accept responsibility for the use of their product. Table 11 shows the character of oil recommended for various conditions of service.

Greases may be used throughout the range shown in Table 11 provided they are selected to meet the operating temperature of the bearing. The heavier oils are used for the higher bearing temperatures and suitable greases must have a corresponding temperature range. It is suggested that generally a grease with A.S.T.M. penetration 225 to 275 can be used where a light or medium oil is specified, and a stiffer or high temperature grease, A.S.T.M. penetration 150, where heavy and extra heavy oil is called for. See A.S.T.M. Specification for Oils and Greases.

The classification of oils given in Table 11 is arranged according to their viscosities, as

**Table 11.—Oil Lubrication of Ball Bearings**

| Bearing Load,* lb. | Revolution per minute | | | | | |
|---|---|---|---|---|---|---|
| | 100 | 300 | 600 | 1200 | 1800 | 3600 |
| 50 | light | light | light | light | medium | medium |
| 100 | light | light | light | medium | medium | medium |

| 2,000 | medium | medium | heavy | heavy | extra heavy | ........ |
| 5,000 | medium | heavy | heavy | extra heavy | ........ | ........ |
| 7,500 | heavy | heavy | extra heavy | ........ | ........ | ........ |
| 10,000 | heavy | extra heavy | ........ | ........ | ........ | ........ |
| 15,000 | extra heavy | extra heavy | ........ | ........ | ........ | ........ |

* Loads given in the table are radial loads only. For thrust loads multiply the actual thrust load by 4 and enter the table with this value of load.

determined by a Saybolt Standard Universal Viscosimeter at 100 deg. F., as follows: Extra light, 135–165 sec.; light, 180–220 sec.; medium, 270–330 sec.; heavy, 360–440 sec.; extra heavy, 450–550 sec.; steam cylinder and valve oils, 2000–2500 sec.

**MAINTENANCE.**—When proper judgment is shown in the design of a ball bearing application, successful operation depends largely on the degree of care exercised in maintenance. Mechanical equipment usually deteriorates more rapidly from neglect than from normal wear and tear in service. The precision and finish with which a ball bearing is manufactured is essential to its best performance, and these qualities will be retained only when the bearing is protected from the accumulation of dirt, rusting in the presence of water and corrosion from chemical action. Lubrication adequate in quality and quantity is necessary, and its provision is a responsibility of the user contributing directly to successful operation.

Bearings mounted in equipment which will be stored for an indefinite period before being placed in service should be protected by use of anti-rust compounds or slushing greases. Lubricating greases generally are inadequate for this purpose, and their use is productive of trouble due to the tendency to separate and harden when the equipment remains idle for protracted periods.

## 9. CYLINDRICAL AND SPHERICAL ROLLER BEARINGS

The demand made by heavy duty requirements has led to the development of additional bearing types that will *interchange* with ball bearings both in dimensional standards and design practice. Cylindrical roller bearings, Figs. 10–12, and spherical roller bearings, Fig. 9, serve this purpose and find their principal use under service conditions that lie beyond the inherent capacity of ball bearings. Cylindrical bearings are used on aircraft engine crank-shafts, railway traction motors, machine tool spindles, and in other applications where their load capacity, permissible speed, and precision of manufacture are of special advantage. Spherical roller bearings are used under the heaviest load and shock conditions, and find extensive application on railway journals, steel mill rolls, crusher and pulverizer equipment, and in other heavy duty industrial and production machinery.

**STANDARDS.—Cylindrical Roller Bearings** manufactured to dimensions and tolerances conforming with the single-row ball bearing, and light, medium and heavy series are listed in Table 6.

**Spherical Roller Bearings** are made in dimensions and tolerances conforming with the Int. Stds. Assoc. wide type, and are listed in Table 7. Other series are available in dimensions adapted to particular requirements. Information concerning these can be obtained from the manufacturer.

**BEARING TYPES.—Cylindrical Bearings** take their name from the cylindrical shape of the roller and raceways. Guide flanges integral with the inner race, type N, Fig. 10, or the outer race type, NU, Fig. 12, serve to constrain the roller and prevent skewing. A suitable cage or retainer is used to space the rollers and to retain them when the inner and outer races are separated in handling. The NF, Fig. 11, type has a flange integral with the outer race, which provides for endwise location and is capable of supporting a moderate thrust load component. The types shown are those found in general use. Modified constructions have been developed to serve special purposes.

**Spherical Roller Bearings,** Fig. 9, are named in consideration of the outer race roller path, which is a spherical surface having its center at the geometrical center of the bearing. The rollers are barrel shaped and have a line contact with the inner race roller path. The in-board end of the roller abuts against a guiding surface on the center flange. The cage or retainer is centered on this flange. The bearing is self-aligning and inherently provides for equalization of radial load between the two rows of rollers. This type of bearing affords a maximum load capacity within given space limitation. Although primarily suited for radial load it has a substantial thrust capacity, in both directions, by virtue of the angular contact of the rollers with the raceways.

**DESIGN PRACTICE.**—**Cylindrical Roller Bearings** are used in accordance with the design principles that apply with ball bearings. They may be operated at essentially the same speeds and have corresponding requirements in the matter of lubrication.

The separable feature of the bearing offers attractive possibilities in assembly procedure, and permits the use of press fits in mounting both inner and outer race. The heavier classes of fit generally should be employed, in view of the inherently greater shock- and load-carrying ability of the bearing. Open type bearings N and NU provide a free endwise float within the bearing, and the choice between these two types depends largely on assembly requirements.

The cylindrical bearing is in effect a rigid unit and due consideration should be shown for the problem of limiting shaft and housing deflection, and to maintaining correct alignment in assembly of the machine parts.

**Spherical Roller Bearings** serve as a self-contained, self-aligning, combined thrust and radial load carrier. Operating speeds are limited to lower values than for the cylindrical type. The lubricant used must gain access to the bearing and penetrate to the center guide flange of the inner race. Both grease and oil are successfully used, but careful consideration should be shown in the selection of lubricant to provide properly for the operating temperature and conditions affecting the supply of lubricant to the bearing.

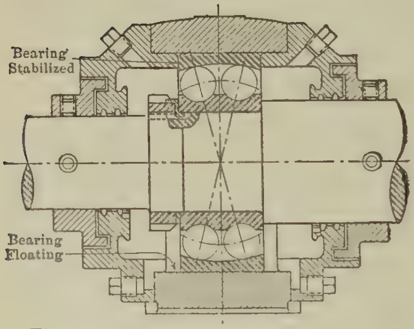

Fig. 16. Pillow Block with Self-aligning Ball Bearing

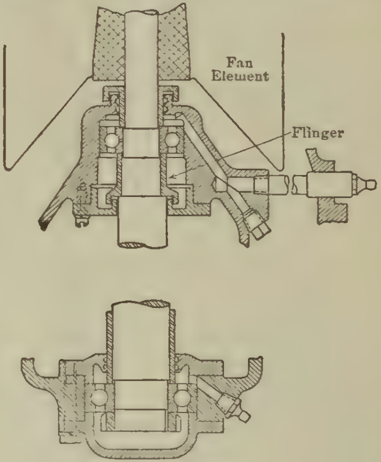

Fig. 17. High-speed Vertical Mounting

This bearing is used to carry the heaviest loads and shocks, and the shaft and housing fits used should be selected accordingly. The aligning feature is of particular value in providing for shaft and housing deflection occurring under load, and at the same time allows for a reasonable degree of incidental misalignment.

**SELECTION OF BEARING SIZE.**—The procedure followed in the selection of cylindrical and spherical bearing sizes is precisely the same as that used with ball bearings. Reference ratings shown in Tables 6 and 7 have been prepared on the same basis, and equations [1] to [5] relating load and speed to reference rating and design life are directly applicable. A graphical solution can be made by means of the chart, Fig. 15, but it should be noted that the speed limit line does not apply for the spherical bearing. When loads and reference ratings lie beyond the range of the chart scales, the decimal point can be shifted simultaneously in both the load and rating, to bring the values within the range of the chart.

In general, cylindrical and spherical bearings are used in the heavier and more complex types of equipment, where experience is of increased importance in design. The bearing manufacturer should be consulted in reference to technical problems of application, so that full advantage can be taken of the experience already gained in highly specialized fields.

## 10. TYPICAL APPLICATIONS

**PILLOW BLOCK.**—Fig. 16 shows a typical pillow block application of a self-aligning ball bearing. The inner ring is a press fit on the shaft seat and the lock-nut clamps the ring against the shaft shoulder. It is important that the shaft fillet at the shoulder clears the corner of the bearing; suitable fillet radii are tabulated in Tables 1 to 7. Manufacturers' catalog data can be consulted for detailed information as to limiting sizes of shaft shoulder, which should provide a flat surface for seating beyond the fillet and at the same time permit access to the face of the ring in order to facilitate removal.

The housing shown is designed for either grease or oil lubrication. Pipe plugs in the top section of the end covers provide for replenishment of the lubricant and drain plugs in the lower section provide for removal of used lubricant. End covers are designed to afford a reservoir capacity for the lubricant. Grooves in the end covers form a shaft enclosure that will prevent leakage from the housing under normal conditions. The inboard grooves have drain slots at the lowest position, to relieve any accumulation of lubricant. The shaft flingers, mounted external of the housing, provide a labyrinth enclosure which is an effective protection against entrance of dust, dirt, or water into the housing. The labyrinth seal depends on a close running clearance and is not subject to deterioration in service.

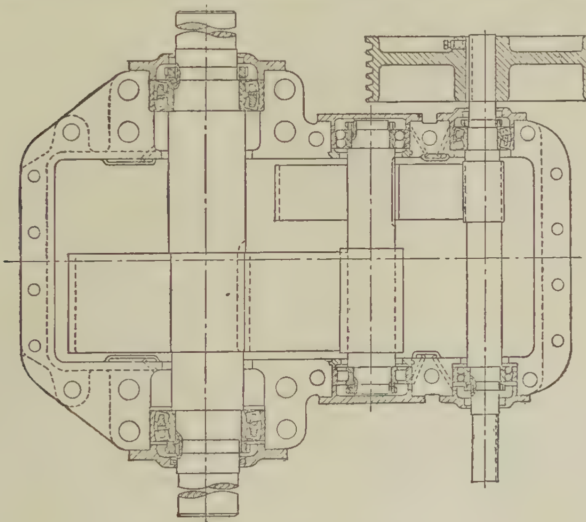

Fig. 18. Heavy-duty Gear Reduction Unit

The alternative designs for free or held bearings allow for axial float or stability. A general principle in the application of bearings is that but one bearing on any shaft is to be stabilized axially, in order to prevent undue thrust reactions as the result of temperature expansion or assembly errors.

**VERTICAL MOUNTING.**—Fig. 17 illustrates a high-speed vertical mounting on a fan, designed for grease lubrication. The lubricant is supplied above the bearing and a reservoir space provided below for its accumulation. Pressure-type grease fittings are used, but it is imperative in such installations to guard carefully against overcharging with grease by indiscriminate application. An internal type of labyrinth seal is provided at the lower shaft enclosure of the upper bearing housing to prevent leakage of lubricant. The external labyrinth flinger at the upper bearing tends to prevent lubricant leakage as the result of air blast induced by the fan element.

**GEAR REDUCTION UNIT.**—Fig. 18 shows a heavy-duty gear reduction unit. The gear case is split on the horizontal center line to facilitate assembly. Spherical roller bearings are used where the loads are heaviest and self-aligning ball bearings to compensate for shaft deflections under load. The open type NM cylindrical roller bearing used on the intermediate shaft provides for free axial float under the relatively heavy load from the adjacent pinion. The bearings are lubricated by oil from the gear case which is trapped on the bosses shown, when thrown from the gears, and fed through the drilled passages to each of the bearings. Leather cuff-type seals seal the case where the shaft passes through.

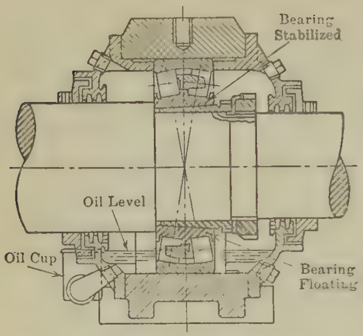

**Fig. 19.** Bearing with Adapter Sleeve

**ADAPTER SLEEVE.**—Fig. 19 shows a convenient type of mounting for the inner race where assembly conditions or service requirements preclude a press fit. The "push in" adapter sleeve is slotted lengthwise so that when it engages the tapered bore of the inner ring it will close in and clamp the shaft seat with an effect equivalent to that of a press fit. The sleeve is withdrawn at disassembly by a removal nut engaging the thread on the shoulder of the sleeve. This construction affords an additional opportunity of controllling internal clearance of the bearing to suit particular requirements.

# ROLLER BEARINGS

By Robert Thurston Kent

Roller bearings are of two general types, straight and tapered. The straight bearing will sustain radial loads only. The tapered bearing will sustain both radial and thrust loads. Straight roller bearings have rollers that are solid steel cylinders, or rollers formed of a flat strip of steel wound in a helix. Needle bearings are one form of straight roller bearings.

## 1. STRAIGHT ROLLER BEARINGS

**WOUND ROLLERS.**—One form of straight roller bearing made by the Hyatt Roller Bearing Co. uses a roller formed by helically winding into a hollow cylinder strips of alloy steel, which then are heat treated and ground to size. Rollers wound right and left hand are assembled alternately in the bearing, and held in proper alignment by a cage retainer. Bearings are made with both solid inner and outer races, with solid outer race and no inner race, and with a split outer race and no inner race. See Tables 1 and 2 for dimensions and capacities. The load ratings in these tables are based on a temperature of 350° F. For temperatures above 350°, the ratings should be multiplied by the following factors:

| Maximum temp., deg. F. . . . . . . | 350 | 400 | 450 | 500 | 550 | 600 |
|---|---|---|---|---|---|---|
| Temp. factor *T*. . . . . . . . . . . . . . . | 1.00 | 0.87 | 0.73 | 0.60 | 0.47 | 0.33 |

For certain classes of service, depending on load fluctuations, shock, overloads, etc., the load ratings should be reduced or increased by multiplying by the following factors:

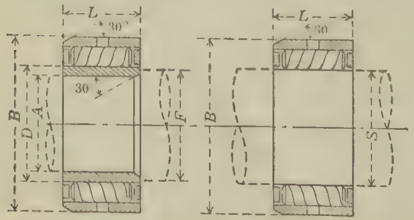

**Fig. 1.** Wound Roller Type Roller Bearing with Solid Outer Race

**Table 1,** 0.67–1.0, agricultural equipment, trailer trucks; 0.80–1.0, hand-operated hoists; 0.80, power-house cranes; 1.0–1.33, centrifugal extractors, electric motors, industrial locomotive journals and transmissions; 1.33, mining machinery, except mine cars; 1.33–2.0, air compressors, hot-saws, sprayers and dusters; 1.0–2.0, dairy machinery; 2.0, house lighting units; 5.0, tractor crawler tracks.

**Table 2,** 0.25, pintle bearings; 0.4–0.67, hand trucks; 0.5–0.67, industrial car caster wheels; 0.80–1.0, hand-operated cranes and hoists; 0.67, steel mill cars, charging cars, ingot cars; 0.67–1.0, agricultural equipment, gravity conveyors, industrial cars, contractors' cars; 0.80–1.0, hand-operated hoists; 1.33, mining machinery, except cars; 2.0–2.8, belt conveyor idlers, rotating shafts; 3.0, soaking pit covers; 3.0–4.0, belt conveyor idlers, stationary shafts. For unusual conditions the manufacturer should be consulted for the proper load rating.

**Lubrication** of wound roller bearings depends on the speed and temperature. The Hyatt Roller Bearing Co. gives a chart showing the range of speeds for various shaft

| 32–150 | 5–8 | 9–12 | 275–325 | 475–525 |  |

diameters, by which a bearing can be classed as low, medium or high speed. From this chart the following figures are taken:

| Shaft diam, in. | $^1/_4$ | $^1/_2$ | 1 | $1\,^1/_2$ | 2 | $2\,^1/_2$ | 3 | 4 | 5 | 6 | 8 | 10 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Low speed, max. r.p.m. | 865 | 755 | 570 | 420 | 310 | 250 | 200 | 165 | 145 | 120 | 90 | 72 |
| Medium speed, max. r.p.m | 3140 | 2820 | 2295 | 1875 | 1535 | 1245 | 1030 | 785 | 645 | 535 | 380 | 325 |

Tables 3 and 4 give the specifications for oil and grease for these bearings, as recommended by the maker. In general, the lightest oil that will stay in the housing should be used. Lubricants heavier than light liquid grease are inadvisable, but when their use is necessary, speeds should be under 300 r.p.m., with temperatures between 50 and 100° F.

**SOLID ROLLER BEARINGS.**—Solid roller bearings comprise a series of solid cylindrical rollers confined between inner and outer raceways, and held in position relative to each other by cages or spacers. The inner raceway frequently is grooved to prevent endwise movement of the rollers. In some cases the inner raceway may be the shaft or spindle itself. The outer raceway may be a plain ring. The rollers then are free to move endwise across the face of the raceway, thus permitting endwise movement of the shaft, or the outer raceway may have a single lip or two lips, forming a groove in the raceway, thus locating the shaft endwise. The outer raceway may be turned to the surface of a sphere, and enclosed in a ring with a spherical interior surface, making a self-aligning bearing. Various forms with their dimensions are shown in Table 5. Table 6 gives dimensions and shows the form of lock nut and lock washer for fastening the bearings to the shaft.

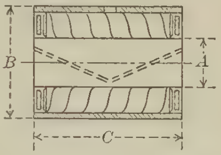

Fig. 2. Wound Roller Type Roller Bearing with Split Outer Race

## 2. NEEDLE BEARINGS

**NEEDLE OR QUILL BEARINGS.**—Needle bearings are straight roller bearings in which diameter of roller is not over $^1/_8 \times$ roller length. Separate outer and inner raceways may be used, or the inner raceway may be the shaft and the outer raceway integral with the structure. These bearings are used where high load-carrying capacity is required in a small space. Load-carrying capacity depends on hardness of the raceways and rollers. Bantam Ball Bearing Co. recommends a hardness, Rockwell C scale, of 56 to 60 for rollers, and of 58 to 60 for raceways. For hardness of less than 58–60 of either raceway, the rated load should be multiplied by the following factors:

| Rockwell hardness, C scale | 60 | 58 | 56 | 54 | 52 | 50 |
|---|---|---|---|---|---|---|
| Rated load factor | 1.00 | 0.96 | 0.91 | 0.81 | 0.70 | 0.50 |

The following formulas may be used in the design of needle bearings: Let $L$ = rated safe load on bearing, lb.; $D$ = diam. of shaft or inner raceway, in.; $D_p$ = pitch diam., in.; $d$ = diam. of roller, in.; $l$ = effective length of roller, in.; $C$ = circumferential clearance on pitch diameter; $S$ = speed of bearing, r.p.m.; for oscillating bearings $S$ may be taken as 8; $K$ = a constant (Table 7). Then

$$L = (10{,}000\,Nld)/\sqrt[3]{S} \quad . \quad . \quad . \quad [1]; \quad N = \pi(D + d)/d \quad . \quad . \quad . \quad . \quad [2]$$

$$D_p = Kd + (C/\pi) \quad . \quad . \quad . \quad . \quad [3]; \quad D = D_p - d \quad . \quad . \quad . \quad . \quad . \quad [4]$$

$C$ ranges from a minimum value of 0.0001 in. per roller to values of greater than $d$. For rotation, $C$ should be increased with $N$ by 0.5 $d$ when $N$ = 20 to 0.9 $d$ when $N$ = 50. For oscillating motion, $C$ may be kept close to minimum values.

An approximate value of $N$ is found by assuming $D$ and $d$. The value of $K$ corresponding to $N$ then is taken from Table 7 and $D_p$ calculated (formula [3]); the maximum value of $D$ then is found by formula [4]. Diametral clearance should be subtracted from the value of $D$ so found. Bantam Ball Bearing Co. recommends the following

| Shaft diam., in. | up to 2 | 2–4 | 4–6 |
|---|---|---|---|
| Diametral clearance, in., min. | 0.0005 | .0010 | .0015 |
| Diametral clearance, in., max. | 0.0015 | .0020 | .0025 |

Bore of outer raceway = $D_p + d +$ diametral clearance. The manufacturing tolerance of the outer raceway should be $+ 0, - 0.0005$ in.

Table 8 gives standard sizes of rollers for quill bearings. Several rows of rollers may be placed in one bearing to obtain the necessary length of roller. The rows should be separated by hardened and ground retaining rings. Longitudinal clearances of from 0.010 to 0.030 in. are required for each set of rollers.

## 3. TAPERED ROLLER BEARINGS

The principle of the tapered roller bearing is essentially a construction of the rolling members and raceways on the elements of a cone, so that lines coincident with the working surfaces of rollers and races all meet at a common point on the axis of the bearing. See Fig. 3. True rolling motion thus is obtained, and the bearing will handle radial or thrust loads or any combination of them. The essential parts are an inner raceway, or cone, an outer raceway or cup, tapered rollers, and a cage or roller retainer, Fig. 4. The accompanying tables of dimensions and capacities are selected as representing the more generally used bearings. Data regarding other sizes and types may be obtained from manufacturers.

**THE STANDARD BEARING** is made in three basic series, namely heavy, medium and light. These are established by maintaining fundamental relations between the various components of the bearing. The standard, or heavy series, has wide races and long rollers; the light series has narrow races and short rollers; the medium series is an approximate mean between the other two. See Table 9. The standard type of bearing is a general service bearing. It is widely used in automotive vehicles, machinery, farm implements, mining machinery, etc.

**THE STEEP ANGLE BEARING,** Fig. 5 is used in power take-offs, worms and bevel gear shafts, etc., where the thrust load predominates, although there is an appreciable radial load. It is similar to the standard bearing except that the angles of both the raceway and rollers are quite steep. See Table 10.

**FLANGED CUP BEARINGS,** Fig. 6, are used where extreme precision is required as on machine tool spindles. The bearing housing is bored straight through, and a seat faced at right angles to the bore. This face provides a backing for the flange of the cup. This bearing also is used where there is insufficient space for conventional bearing-mounting methods, and where the housing is of manganese steel or other material difficult to machine. Table 11 gives dimensions and capacities.

**MULTIPLE ROW BEARINGS** provide maximum load carrying capacity in small space, resist thrust loads from both directions and maintain a precise and rigid mounting or a floating assembly as desired. They are made in several types as follows:

**Two-row Double-cup Single-cone Bearings,** Fig. 7. Three assemblies are possible. 1. A spacer is introduced between the cones to establish the set-up or running clearances at the time the bearing is assembled. 2. The cones are butted together, thus

establishing the proper running clearance. 3. No cone spacer is used and the proper clearance is obtained by some form of adjusting device. Types 1 and 2 usually are preferred if quick removal and replacement of bearings is necessary, or if operating conditions do not necessitate take-up after a long period of service. With this type of bearing, shaft expansion is provided for by locking the cone in position and permitting the cup to float in the housing. The opposite end of the shaft usually is fixed in position, and movement is confined to one end. Both conventional and steep-angle assemblies are possible with this bearing. See Table 12.

**Two-row Double-cone Single-cup Bearings,** Fig. 8, are used when the capacity of a two-row bearing is required, with a simpler mounting than two standard single-row bearings. They also are used on the fixed end of a shaft when allowance must be made for shaft expansion. The bearing used on the opposite end then usually is a floating double-cup unit. See Table 13.

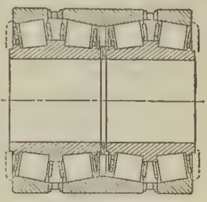

Fig. 9. Four-row Tapered Roller Bearing

**Four-row Bearings,** Fig. 9, are used where maximum capacity is required in a limited space, as in rolling mills, cement plants, rubber mills and other units which develop extreme pressures. It comprises four sets of rollers. The arrangement is similar to two double-cone bearings set side by side with a double cup carrying the load from the two inner sets of rollers and a single cup carrying the load imposed on the two outer sets of rollers. Spacer rings are recommended in all applications. Manufacturers should be consulted regarding application of this type of bearing.

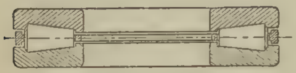

Fig. 10. Tapered Roller Thrust Bearing

**Thrust Bearings** to withstand thrust loads only without radial loads are shown in Fig. 10.

**LOAD FACTORS FOR TAPERED ROLLER BEARINGS.**—The load ratings for tapered roller bearings as given in the tables can be converted to ratings at speeds other than 500 r.p.m. by application of the factors given in Table 14.

**Life and Service Factors.**—The rating of the bearings given in Tables 9 to 13, are based on a life expectancy of 3000 hours of service. For longer life, the loads given in the tables must be reduced by an appropriate factor. Also for certain classes of service involving shock, inequality of loading, intermittent operation, etc., the load rating must be modified by an application factor. The two factors are combined in a service factor by which the rated load should be multiplied as follows: 0.8, steel mill machinery; 0.67, belt drives, farm tractor transmissions, gas or oil engines for farm use, gear reduction drives, I-beam trolleys, railway section cars, shop trucks and trailers; 0.57, automotive wheels and differentials; 0.50, dough mixers, elevators, industrial steam engines, fans and blowers, farm machinery, except tractor transmissions, garage compressors, glass making machinery, grain milling machinery, highway trailers, I-beam cranes and hoists, ice-making machinery, laundry machinery, leather working machinery, locomotives, mine and industrial, logging engines, machine tools, pulverizing and screening equipment, pumps, deep-well and fire, railway car drives, road building machinery, saw mill and woodworking machinery, stokers, textile machinery; 0.4, special motors and generators; 0.33, air compressors, clay working machinery, dredge pumps, printing machinery, rubber machinery; 0.25, paper mill machinery and pumps.

Fig. 11. Timken Lock Nuts

METHODS OF MOUNTING TAPERED ROLLER BEARINGS.—Fig. 11 shows various methods of mounting tapered roller bearings. Design 1 is for those cases where the maximum possible shaft extension diameter is desired. In Design 2 it is possible to use a smaller size nut than in Design 1, and yet have the necessary cone backing. Design 3 uses a single lock-nut and tongued washer to clamp another member through the cones.

**Table 15.—Shaft Lock-nuts and Washers for Tapered Roller Bearings**

A small spacer is necessary between the front face of the cone to prevent interference by the washer with the bearing cage. The diameter of the spacer must be such as to provide cage clearance. In Design 4 the nut should provide sufficient backing to clamp the assembly solidly. Design 5 is a typical automotive application. A hardened tongued washer is used between the inner nut and cone face. The length of thread and keyway must be increased by the thickness of the hardened washer. Table 15 gives dimensions of lock-nuts and tongued washers. For data concerning the theory of tapered roller bearings and their application to various services consult the Timken Engineering Journal published by the Timken Roller Bearing Co., Canton, Ohio.

**LUBRICATION.**—Table 16 gives the specifications of lubricants recommended for tapered roller bearings by the Timken Roller Bearing Co. In general, bearings less than 6 in. outside diam., operating at speeds of less than 1000 r.p.m., without unusual conditions may be lubricated with a lime or soda base grease of medium consistency. With moisture present, only a lime base should be used. For speeds above 1000 r.p.m., oil is more satisfactory, but grease may be used on the smaller bearings. Grease is recommended for bearings over 6 in. outside diam. only up to 500 r.p.m. High-speed bearings are best lubricated with light oil and a drop feed or wick system, with provision to drain excess oil to avoid heat due to churning. The drain should be so located that the lowest point of the bearing is not immersed more than 1/8 in. A circulating oil system is recommended for conditions of extreme heat. For unusual conditions, advice as to lubrication should be obtained from the makers of the bearings.

For general machinery applications, grease should be compounded from a high grade soap and a refined mineral oil, free from acid, alkali, and fillers that would tend to score the bearing. A bright copper or steel plate, submerged in the grease for 24 hr. should show no discoloration. Ash and moisture should not exceed 2%. Oil from which the grease

# GEARING

Rewritten by **Earle Buckingham**

## 1. FRICTION GEARING

**FRICTION GEARING.**—If two cylinders with parallel axes are in contact and one of them rotates upon its axis, the friction between the surfaces will drive the other cylinder. The driving capacity depends upon the coefficient of friction of the material of the wheels, the pressure with which they are held in contact, and the length of the cylinders. In order to secure good frictional conditions, one member only of a friction gearing is of iron; the other is of a composition giving a high coefficient of friction with iron. The composition wheel is always the driving member, and its slip on the driven tends to distribute the wear uniformly over its surface. Friction gearing cannot be used if positive driving is essential, as it is always liable to slip. It may be used where the power to be transmitted is not very great; where the speed is so high that toothed wheels would be noisy; where the shafts are frequently to be put in and out of gear or to have their relative directions of motion reversed; or where the velocity ratio is to be changed while the machinery is in motion.

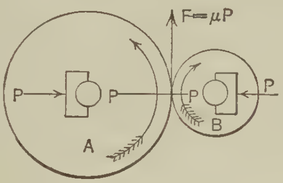

Fig. 1. Forces in Plain Friction Gearing

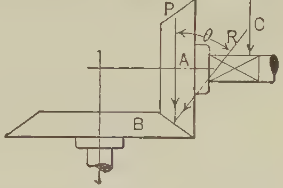

Fig. 2. Forces in Bevel Friction Gearing

**POWER TRANSMITTED BY FRICTION WHEELS.**—The tangential force that can be transmitted by two friction gears is equal to the product of the total normal pressure and the coefficient of friction. Thus, in Fig. 1 let $P$ = total normal pressure, lb.; and $\mu$ = the coefficient of friction; then, $F$, the resultant tangential force $= \mu P$. If $V$ = velocity of the surface of the friction wheels, ft. per min., the horsepower transmitted is Hp. $= \mu PV/33000$. If $d$ = diameter of the driver, in.; $l$ = length of the face, in.; $w$ = allowable load per inch of face, lb.; $N$ = revolutions per minute,

$$\text{Hp.} = (\mu wl \times 3.1416\, dN) \div (12 \times 33000) = 0.000008\, \mu wldN.$$

In *bevel wheels*, Fig. 2, the resultant $R$ of the applied force $P$ presses the wheels together, and $R = P \div \cos\theta$. The velocity of the mean circumference of the driver may be taken as the velocity of transmission.

**WEDGE-FACED OR GROOVED FRICTION WHEELS** give greater resistance to slipping with a given radial pressure. In Fig. 3, $P$ = the radial force applied to the grooved surfaces, lb.; $F$ = the tangential force transmitted, lb.; $R/2$ = the reaction on each face; and $2\theta$ = the angle of the groove; the wedge is held in equilibrium by the force $P$, the reactions $R/2$ and the frictional resistance $\mu R/2$ due to the wedging action. Then $R = F/\mu$; $P = F\sin\theta/\mu + F\cos\theta$; $F = \mu P/(\sin\theta + \mu\cos\theta)$. As before, the tangential force that can be transmitted by the gears is the product of the total normal pressure and the coefficient of friction. The number of wedges has no influence on the power transmitted, but decreases the wear by distributing it over several surfaces.

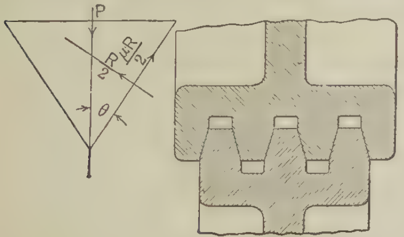

Fig. 3. Forces in Grooved Friction Wheels

The angle $2\theta$ of the grooves varies from 30° to 40°, but to avoid sticking should never be less than 30°. (See Kimball & Barr, Machine Design.)

**POWER TRANSMITTED BY FRICTION DRIVES.** (W. F. M. Goss, *Trans.* A. S. M. E., 1907.)—Driving wheels of each of the materials named in Table 1 were tested in peripheral contact with driving wheels of iron, aluminum and type metal. All the wheels were 16 in. diam.; the face of the driving wheels was 1 $^3/_4$ in., and that of the driven wheels $^1/_2$ in. Records were made of the pressure of contact, of the coefficient of friction developed, and of the percentage of slip resulting from the development of the coefficient of friction. Curves were plotted showing the relation of the coefficient and the slip for pressures of 150 and 400 lb. per inch width of face in contact. Another series of tests was made in which the slip was maintained constant at 2% and the pressures were varied. In most of the combinations it was found that with constant slip the coefficient of friction diminished very slightly as the pressure of contact was increased, so that it may be considered practically constant for all pressures between 150 and 400 lb. per sq. in.

The crushing strength of each material under the conditions of the test was determined by running each combination with increasing loads until a load was found under which the wheel failed before 15,000 revolutions had been made. The results showed the failure of the several fiber wheels under loads per inch of width as follows: Straw fiber, 750 lb.; leather fiber, 1200 lb.; tarred fiber, 1200 lb.; leather, 750 lb.; sulphite fiber, 700 lb. One-fifth of these pressures is taken as a safe working load. The coefficient of friction approaches its maximum value when the slip between driver and driven wheel is 2%. The safe working horsepower of the drive is calculated on the basis of 60% the coefficient developed at a pressure of 150 lb. per inch of width, a reduction of 40% being made to cover possible decrease of the coefficient in actual service and also to cover loss due to friction of the journals. From these data Table 1 is constructed showing the horsepower that may be transmitted by driving wheels of the several materials named when in frictional contact with iron, aluminum and type metal.

The formula for horsepower is Hp. = $(\pi d/12) \times (WPN \times 0.6f/33000) = KdWN$, in which $d$ = diam., in.; $W$ = width of face, in.; $P$ = safe working pressure, lb. per in. of width; $N$ = revs. per min.; $f$ = coefficient of friction; 0.6 = a factor for the decrease of the coefficient in service and for the loss in journal friction; $K$ = a coefficient including $P$, $f$ and the numerical constants.

**Table 1.—Coefficients of Friction and Horsepower of Friction Drives**

| | On Iron | | On Aluminum | | On Type Metal | |
|---|---|---|---|---|---|---|
| | $f$ | $K$ | $f$ | $K$ | $f$ | $K$ |
| Straw fiber | 0.255 | 0.00030 | 0.273 | 0.00033 | 0.186 | 0.00022 |
| Leather fiber | 0.309 | 0.00059 | 0.297 | 0.00057 | 0.183 | 0.00035 |
| Tarred fiber | 0.150 | 0.00029 | 0.183 | 0.00035 | 0.165 | 0.00031 |
| Sulphite fiber | 0.330 | 0.00037 | 0.318 | 0.00035 | 0.309 | 0.00034 |
| Leather | 0.135 | 0.00016 | 0.216 | 0.00026 | 0.246 | 0.00029 |

## 2. TOOTHED WHEEL GEARING

**DEFINITIONS OF TOOTH PARTS.** (See Fig. 4.)—**Addendum Circle** is the circle which limits the tops of the teeth.

**Pitch-circle** is the trace of the pitch cylinders on which the tooth curves are formed.

**Dedendum or Root Circle** is the circle which limits the bottom of the tooth.

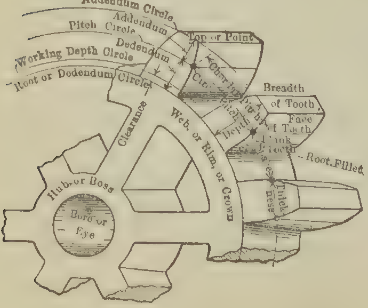

FIG. 4. Nomenclature of Gearing

**Clearance** is the amount by which the tops of the teeth of one wheel clear the bottoms of the spaces of the other, as they pass the line of centers.

**Working Depth Circle** is a circle of radius equal to that of the dedendum circle plus the clearance.

**Face** is that part of the tooth lying between the pitch and addendum circles.

**Flank** is that part of the tooth lying between the pitch and dedendum circles.

**Thickness** of the tooth is its width measured on the pitch circle.

**Width of Space** is the space between the teeth measured on the pitch-circle.

**Backlash** is the difference between the thickness of a tooth and the space into which it meshes, measured on the pitch-circles.

**Pitch Diameter** is the diameter of the pitch-circle. It is the diameter that is used in making all calculations for the size of gears.

**Circular Pitch** is the distance in inches between similar points of adjacent teeth, measured along the pitch-circle. It is the thickness of the tooth plus the width of a space, measured on the pitch-circle.

**Diametral Pitch** is the number of teeth on the gear per inch of diameter of the pitch-circle.

Circular pitch × diametral pitch = $\pi$.

**Diameter Pitch or Module** is the distance in inches obtained by dividing the diameter of the pitch-circle by the number of teeth in the gear.

**Chordal Pitch** is the length of a straight line drawn from the pitch points of two adjacent teeth. Chordal pitch = diam. of pitch-circle × sine (180° ÷ No. of teeth). Chordal pitch is used with chain or sprocket wheels, to conform to the pitch of the chain.

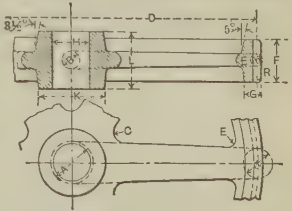

Fig. 5. Proportions of Spur Gears

**Angles of Action** are the angles through which the gears turn while a pair of teeth are in action. If the diameters are not alike, these angles will be inversely as the radii of the pitch-circles, since the arcs which subtend them are equal.

**Angle of Approach** is the angle through which a gear turns from the beginning of contact of a pair of teeth until contact reaches the pitch point.

**Angle of Recess** is the angle through which a gear turns while the contact point of a pair of teeth moves from the pitch point to the point where the teeth pass out of contact. Angle of Approach + Angle of Recess = Angle of Action.

**Line of Action** is a line normal to the tooth curves at their point of contact.

**Angle of Obliquity** is the angle which any line of action makes with the common tangent to two pitch-circles. This is constant for the involute system, and is commonly called the pressure angle.

**STANDARD PROPORTIONS FOR SPUR GEARS.** (Brown & Sharpe Mfg. Co., Providence.)—A regular system of proportioning gears must be followed, if the gears are to have good proportions, sufficient strength without excessive weight, and uniform appearance when the gears are used in sets. The following formulas, and Table 2, refer to Fig. 5, and are for gears of from 4 in. diameter, 20 diametral pitch to 72 in. diameter, 1 ½ diametral pitch. $D$ = pitch diameter, $P$ = diametral pitch, $d$ = dedendum, $f$ = addendum, and $t$ = thickness of tooth at pitch line. The significance of the other factors in the formulas is shown in Fig. 5.

**Table 2.—Values of $\{(0.95/P) + 0.28\}$ for Finding $A$**

| Diametral pitch | 1 | 1 1/2 | 2 | 2 1/2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 |
|---|---|---|---|---|---|---|---|---|---|---|---|
| $(0.95/P) + 0.28$ | 1.23 | 0.915 | 0.755 | 0.660 | 0.597 | 0.520 | 0.470 | 0.44 | 0.42 | 0.40 | 0.39 |
| Diametral pitch | 10 | 11 | 12 | 13 | 14 | 15 | 16 | 17 | 18 | 19 | 20 |
| $(0.95/P) + 0.28$ | 0.38 | 0.37 | 0.36 | 0.354 | 0.352 | 0.345 | 0.340 | 0.337 | 0.334 | 0.332 | 0.330 |

### Formulas for Proportions of Spur Gears

Proportions of Arm.

$A = 0.138D\{(0.95/P) + 0.28\} + 0.67.$

$a = {}^2/_3 A.$

$B = 0.4A.$

$b = 0.4a$ or ${}^2/_3 B.$

$C = {}^1/_4 A.$

Proportions of Hub.*

$K = 1.5H + {}^1/_4$ in.† $L = 1.5H.$

Proportions of Rim.

* $F = (8/P) + 0.25.$

$E = {}^1/_4 A.$

$G = (d + f) + t + 0.06.$

$R = {}^1/_{32}$ in. (to 20 pitch incl.); ${}^3/_{64}$ in. (to 14 pitch incl.); ${}^1/_{16}$ in. (to 8 pitch incl.); ${}^3/_{32}$ in. (to 4 pitch incl.); ${}^1/_8$ in. (above 4 pitch).

**To Determine Whether Gears Shall Be Solid, Web, or Arm.**— Gears to be used together should be consistent as to construction. Table 3 shows the maximum diameter that should be used in each style of gear. Diameters greater than those shown in the "Web" column should be made with 6 arms, of the proportions given by formulas above.

---

* Suitable for general practice. For light change gears $F$ should be less than given by formula. The hole $H$ should vary to suit conditions, but can usually be made to agree with one of the following formulas:

$$H = (4/P) + 0.5; = (5/P) + 0.5; = (6/P) + 0.5.$$

† Where heavy service is required, or large set-screws or keyways are to be used, make $K = 1.625H + {}^1/_4$ or reinforce hub over keyway or around set-screw.

Table 3.—Maximum Permissible Diameter, In., of Solid and Web Gears

| Diametral Pitch | Solid Gears |  | Web Gears |  | Diametral Pitch | Solid Gears |  | Web Gears |  |
|---|---|---|---|---|---|---|---|---|---|
|  | Change | Combination | Change | Combination |  | Change | Combination | Change | Combination |
| 4 | 5.50 | 6.00 | 9.00 | 9.50 | 10 | 3.80 | 3.80 | 5.80 | 6.00 |
| 5 | 4.80 | 5.00 | 7.50 | 8.00 | 12 | 3.67 | 3.67 | 5.67 | 5.75 |
| 6 | 4.50 | 4.75 | 7.30 | 7.75 | 14 | 3.29 | 3.29 | 5.30 | 5.50 |
| 7 | 4.30 | 4.57 | 6.86 | 7.00 | 16 | 3.13 | ...... | 4.15 | ...... |
| 8 | 4.25 | 4.25 | 6.75 | 6.88 | 18 | 3.00 | ...... | 4.55 | ...... |
| 9 | 4.00 | 4.00 | 6.67 | 6.75 | 20 | 2.80 | ...... | 4.40 | ...... |

For ordinary service, "combination" gears should be used, the "change" gears being adapted only for light service.

**GEAR WHEEL ARMS.**—The proportions of sections for gear wheel arms shown in Fig. 6 are taken from Leutwiler's Machine Design. It is also suggested that the section modulus of the arm at the center of the hub be computed by the formula $I/c = WR/nS$, where $W$ = load on the gear; $R$ = length of arm, or radius of the gear, in.; $S$ = allowable fiber stress of the material; $n$ = number of arms in the gear; $I$ = moment of inertia of section; $c$ = distance of extreme fiber from axis. This formula for the elliptical section gives $I/c = h\sqrt[3]{20WR/nS}$. The dimensions of the arm at the pitch-line can be approximately 0.7 of those at the center.

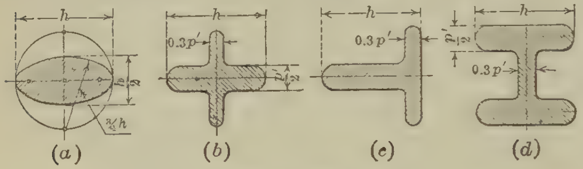

Fig. 6. Forms of Gear Wheel Arms

The number of arms suggested are: 1. For gears up to 16 to 20 in. diameter, 4 or 5 arms; 2. For gears 20 to 60 in. diameter, 6 arms; 3. For gears 60 to 96 in. diameter, 8 arms; 4. For gears over 96 in. diameter, 10 or 12 arms. For small gears web centers of thickness approximately one-half of the circular pitch are recommended.

**WIDTH OF TEETH.**—The width of the faces of teeth generally is made from 2 to 3 times the circular pitch, that is, from 6.28 to 9.42 divided by the diametral pitch. There is no standard rule for width.

The following sizes are given in a stock list of cut gears in "Grant's Gears":

|  |  |  |  |  |  |  |
|---|---|---|---|---|---|---|
| Diametral pitch.... | 3 | 4 | 6 | 8 | 12 | 16 |
| Face, inches....... | 3 & 4 | 2 1/2 | 1 3/4 & 2 | 1 1/4 & 1 1/2 | 3/4 & 1 | 1/2 & 5/8 |

The Walker Company gives:

|  |  |  |  |  |  |  |  |  |  |  |  |  |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Circular pitch, in. | 1/2 | 5/8 | 3/4 | 7/8 | 1 | 1 1/2 | 2 | 2 1/2 | 3 | 4 | 5 | 6 |
| Face, in........ | 1 1/4 | 1 1/2 | 1 3/4 | 2 | 2 1/2 | 4 1/2 | 6 | 7 1/2 | 9 | 12 | 16 | 20 |

## 3. FORMS OF THE TEETH

In order that the teeth of gears and pinions may run together smoothly and with a constant relative velocity, it is necessary that their working faces shall be formed of certain curves called odontoids. The essential property of these curves, of which there is an almost infinite variety, is that when two teeth are in contact the common normal to the tooth curves at their point of contact must pass through the pitch point, or point of contact of the two pitch circles. Any system of such curves can be best defined by the shape of the basic rack, *i.e.*, the rack form that is conjugate to all gears of the system. Because of its greater simplicity of production and control, the involute system, whose basic rack form comprises straight lines, is the one most widely used for power transmission. Other forms are used for special purposes. The cycloidal and pin-tooth forms are widely used in watches, clocks, etc. The four following forms have been standardized by the American Standards Assoc.

1. **THE 14 1/2-DEGREE COMPOSITE SYSTEM** was developed originally by Brown & Sharpe Mfg. Co., for use with its formed gear milling cutters, and has been commonly known as the Brown & Sharpe 14 1/2-deg. involute system. It has proved to be a very satisfactory gear-tooth system for general purposes. Fig. 7 shows the form of the basic

rack and the standard tooth proportions. Gears of this system are generally produced by formed milling cutters, but hobs made to this basic rack form are sometimes used.

**Formed Milling Cutters for 14 $^1/_2$-Degree Composite System.**—Theoretically, a different cutter is required for every different diameter of gear, even though the pitch remains the same. In practice, however, it has been found that the same cutter can be used for several sizes of gears having the same pitch, without serious error. See Table 4. By this plan 8 cutters will cut all gears of 12 teeth and over, of any one pitch. Thus, it takes 8 cutters to cut all 4-pitch gears of 12 teeth or more. A No. 8,

### Table 4.—List of Gear Cutters and Number of Teeth Cut

(Brown and Sharpe Mfg. Co., Providence, R. I.)

| Cutter No. | No. of Teeth | Cutter No. | No. of Teeth | Cutter No. | No. of Teeth | Cutter No. | No. of Teeth |
|---|---|---|---|---|---|---|---|
| 1 | 135–rack | 3 | 35–54 | 5 | 21–25 | 7 | 14–16 |
| 2 | 55–134 | 4 | 26–34 | 6 | 17–20 | 8 | 12–13 |

### Table 5.—Relation of Dimensions of Parts of Gears

(Brown & Sharpe Mfg. Co., Providence, R. I.)

**Notation**—$P$ = diametral pitch; $p$ = circular pitch; $N$ = number of teeth; $D$ = pitch diameter; $d$ = outside diameter; $a$ = addendum; $t$ = thickness of tooth at pitch-line; $r$ = root; $c$ = clearance; $W$ = working depth; $H$ = whole depth.

| Diametral Pitch | | | Circular Pitch | | |
|---|---|---|---|---|---|
| Given | To Find | Formula | Given | To Find | Formula |
| $p$ | $P$ | $P = 3.1416 \div p$ | $P$ | $p$ | $p = 3.1416 \div P$ |
| $D, N$ | $P$ | $P = N \div D$ | $D, N$ | $p$ | $p = D \div 0.3183\,N$ |

| $P$ | $c$ | $c = 0.157 \div P$ | | | |
| $t$ | $c$ | $c = 0.1\,t$ | | | |

### Table 6.—Diameter of Pitch-Line of Wheels from 10 to 100 Teeth of 1 in. Circular Pitch

For diameter of wheels of any other pitch than 1 in., multiply the figures in the table by the pitch. Given the diameter and the pitch, to find the number of teeth: Divide the diameter by the pitch, look in the table under diameter for the figure nearest to the quotient, and the number of teeth will be found opposite.

| No. Teeth | Diam., in. | No. Teeth | Diam., in. | No. Teeth | Diam., in. | No. Teeth | Diam., in. | No. Teeth | Diam., in. | No. Teeth | Diam., in. |
|---|---|---|---|---|---|---|---|---|---|---|---|
| 10 | 3.183 | 26 | 8.276 | 41 | 13.051 | 56 | 17.825 | 71 | 22.600 | 86 | 27.375 |

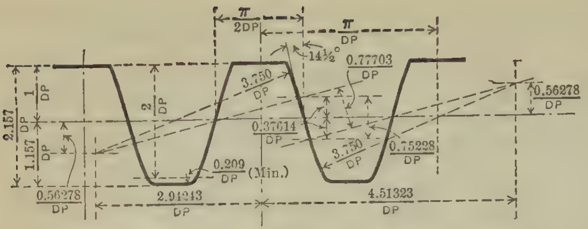

Fig. 7. Basic Rack for 14 1/2-deg. Composite System

5-pitch cutter cuts only 5-pitch gears having 12 or 13 teeth. On each cutter is stamped the numbers of teeth at the limits of its range, and the number of the cutter. When required, the error introduced by the use of range cutters can be minimized by cutting the teeth in mating gears to slightly different depths. See Chap. IV, Spur Gears, Earle Buckingham. (New York, McGraw-Hill Book Co.)

**2. THE 14 1/2-DEGREE FULL DEPTH TOOTH INVOLUTE SYSTEM** was developed for use with gear hobs, for both spur and helical gears. As the useful tooth form cannot exist below the base circle of the involute form, this system should not be used for small numbers of teeth unless a suitable change is made in the tooth proportions of mating gears. See Chap. V., Spur Gears, Earle Buckingham. (New York, McGraw-Hill Book Co.) This system has proved to be a satisfactory form for general purposes for both spur and helical gears. The form of the basic rack and the standard tooth proportions are shown in Fig. 8. The standard tooth proportions of this system are the same as those for the 14 1/2-deg. composite system, and Tables 5, 6, and 9 also apply to it. When the number of teeth in any gear of this system is less than 35, undercut will be present. When the number of teeth is less than 22, the amount of undercut may be enough to reduce the angle of action appreciably.

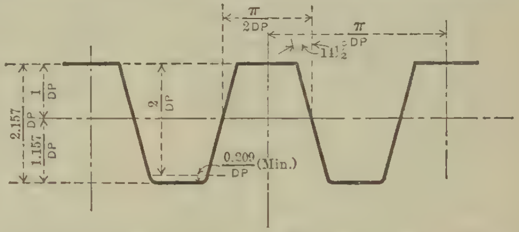

Fig. 8. Basic Rack for 14 1/2-deg. Full Depth Involute System

**3. THE 20-DEGREE FULL DEPTH TOOTH INVOLUTE SYSTEM** was developed for use with hobs and also for use with Fellows gear shapers. The increased pressure

| 9. Radius of Fillet | 1 1/3 × Clearance | | 1 1/2 × Clearance | | 1 1/2 × Clearance | |

* The term Diametral Pitch is used up to 1 $DP$ inclusive and the term Circular Pitch is used for 3 in. $CP$ and over. † A suitable working tolerance should be considered in connection with all minimum recommendations. ‡ Minimum clearance refers to the clearance between the top of the gear tooth and the bottom of the mating gear space, and is specified as *minimum* to allow for necessary cutter clearance for all methods of producing gears. At the present time (1936) this value cannot be standardized.

angle results in stronger tooth forms, and its use is rapidly increasing for general industrial purposes. It is also widely used in automotive construction. The form of the basic rack and the standard tooth proportions are shown in Fig. 9. The standard tooth proportions of this system are the same as those for the 14 1/2-deg. composite system, and Tables 5, 6, and 9 also apply to it. When the number of teeth in any gear of this system is less than 17, undercut will be present. When the number of teeth is less than 14, this undercut may be enough to reduce the angle of action appreciably.

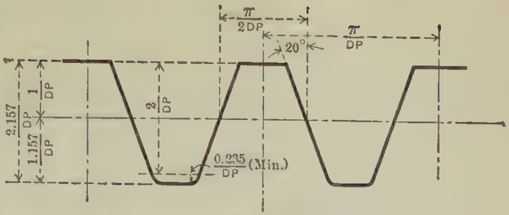

Fig. 9. Basic Rack for 20-deg. Full Depth Involute System

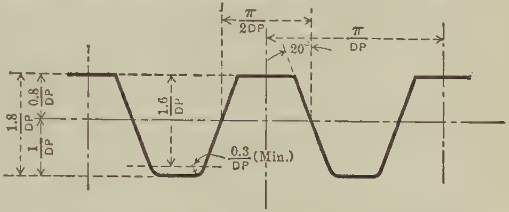

Fig. 10. Basic Rack for 20-deg. Stub Involute System

**4. THE 20-DEGREE STUB TOOTH SYSTEM** originally was developed for heavy duty, generally slow speed, machinery applications in order to obtain the strongest practical tooth forms. It was later adopted for automotive uses where the numbers of teeth were small. Several different stub tooth systems, differing but slightly from each other, have been developed. The basic rack form and tooth proportions shown in Fig. 10 will interchange and operate with all of the 20-deg. stub tooth systems in general use, the only difference being in the amount of clearance. The dimensions of the tooth parts of this system are given in Table 8.

**FELLOWS STUB TOOTH GEAR SYSTEM.**—The 20-deg. stub tooth gear system developed by the Fellows Gear Shaper Co., has been widely used for automobile trans-

missions. The proportions of the teeth are based on two diametral pitches, one of which is used to obtain the dimensions of the addendum and dedendum, while the other is used for the dimensions of the pitch circle and tooth-thickness. These gears are designated by a fraction as $^4/_5$, $^{10}/_{12}$ pitch, etc. The numerator designates the pitch determining the number of teeth and tooth thickness. The denominator designates the pitch determining the height of the teeth. The clearance is (0.25/diametral pitch). Table 10 gives dimensions of Fellows stub tooth gears.

## 4. RULES FOR CALCULATING THE SPEED OF GEARS

The relations of the size and speed of driving and driven gear-wheels are the same as those of belt pulleys. In calculating for gears, multiply or divide by the diameter of the pitch-circle or by the number of teeth.

If $D$ = diam. of driving wheel, $d$ = diam. of driven, $R$ = rev. per minute of driver, $r$ = rev. per min. of driven, $RD = rd$;

$$R = rd \div D; \quad r = RD \div d; \quad D = dr \div R; \quad d = DR \div r.$$

If $N$ = No. of teeth of driver and $n$ = No. of teeth of driven, $NR = nr$;

$$N = nr \div R; \; n = NR \div r; \; R = rn \div N; \; r = RN \div n.$$

To find the number of revolutions of the last wheel at the end of a train of spur-wheels, all of which are in a line and mesh into one another, when the revolutions of the first wheel and the number of teeth or the diameter of the first and last are given: Multiply the revolutions of the first wheel by its number of teeth or its diameter, and divide the product by the number of teeth or the diameter of the last wheel.

To find the number of teeth in each wheel for a train of spur-wheels, each to have a given velocity: Multiply the number of revolutions of the driving wheel by its number of teeth, and divide the product by the number of revolutions each wheel is to make.

To find the number of revolutions of the last wheel in a train of wheels and pinions, when the revolutions of the first or driver, and the diameter, the teeth, or the circumference of all the drivers and pinions are given: Multiply the diameter, the circumference, or the number of teeth of all the driving wheels together, and this continued product by the number of revolutions of the first wheel, and divide this product by the continued product of the diameter, the circumference, or the number of teeth of all the driven wheels, and the quotient will be the number of revolutions of the last wheel.

Example.—1. A train of wheels consists of four wheels each 12 in. diameter of pitch-circle, and three pinions 4, 4, and 3 in. diameter. The large wheels are the drivers, and the first makes 36 revs. per min. Required the speed of the last wheel.

*Solution:*
$$\frac{36 \times 12 \times 12 \times 12}{4 \times 4 \times 3} = 1296 \text{ r.p.m.}$$

2. What is the speed of the first large wheel if the pinions are the drivers, the 3-in. pinion being the first driver and making 36 revs. per min.?

*Solution:*
$$\frac{36 \times 3 \times 4 \times 4}{12 \times 12 \times 12} = 1 \text{ r.p.m.}$$

## 5. ELLIPTICAL GEARS

Elliptical gears give a variable velocity ratio throughout the revolution. They represent a cheap way of obtaining a quick-return motion, and are so used on planers, shapers, slotters and similar cutting tools, and also on pumps, shears, punches and other machines which do their work mostly on the forward stroke of a reciprocating member. To determine the pitch ellipses for any given set of conditions, let $c_1 c_2$, Fig. 11, be the given distance between shaft centers. Divide $c_1 c_2$ at $p$ so that $c_1 p/p c_2$ equals the extreme velocity ratio. Lay off $pa = pc_1$ for the other focus of the lower ellipse. As the ellipses must be equal, lay off $c_1 b = c_2 a$, and $b$ is the other focus of the upper ellipse. The extremity $f$ of the minor axis is found by making $af = fc_2 = {}^1/_2\, c_1 c_2$; any other point on the ellipse, such as $d$, is found by making $ad + dc_2 = c_1 c_2$. The two free foci $a$ and $b$ remain at a constant distance apart during rotation, and are sometimes connected by a link. If $V = R^2/r^2$, $A = {}^1/_2$ major axis of the ellipse and $B = {}^1/_2$ the minor axis, then an equation which gives the ratio of the semi-major and semi-minor axes for a given range of velocity ratio is

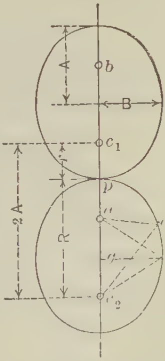

Fig. 11. Laying Out Pitch Ellipses of Elliptical Gears

$$B/A = 2\sqrt[4]{V} \div (1 + \sqrt{V}).$$

See Unwin, Machine Design, and Logue, American Machinist Gear Book.

## 6. EPICYCLIC GEAR TRAINS

Epicyclic Gear Trains may be defined as trains of wheels in which some or all of the wheels have a motion compounded of a rotation about an axis and a revolution, or translation, of that axis. (Schwamb, Merrill & James, Elements of Mechanism.) They are used to produce high velocity ratios with few parts. The link is usually called the train arm; it often rotates upon the axis of the first wheel of the train. The last wheel of the train may or may not be placed upon this axis. The name epicyclic has no connection with the form of the gear teeth which may be of the cycloidal, involute or any other system.

**METHODS OF SOLUTION OF GEAR TRAINS.**—These trains may be solved by two methods: 1. By resolving the resultant motion into its components and then allowing these to take place in succession, the motion of the arm being considered first. For example: If in Fig. 12, *A* has 100 teeth and *B* has 50; and if *A* makes +5 turns about the fixed axis *a* while the arm *D* makes −6 turns, the number of turns of *B* is found as follows:

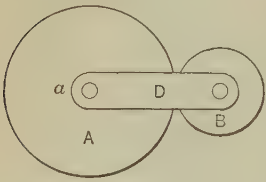

FIG. 12

Suppose the mechanism locked so that the wheels cannot turn in relation to the arm, and then turn the whole −6 turns about *a*, the number of turns which the arm is to make. Next consider the train unlocked, and put the wheel for which the motion is given, in this case *A*, where it should be. *A* is to make +5 turns, but it has been turned −6 turns with the arm when the train was locked; it must now be turned +11 in order that its resultant turns shall be +5. This will cause *B* to make −22 turns, since the value of the train (turns *B*)/(turns *A*) = − 2. Next, take the algebraic sum of the above component motions. Thus:

| | *A* | *B* | Arm |
|---|---|---|---|
| 1. Train locked........................... | − 6 | − 6 | −6 |
| 2. Train unlocked, arm fixed................ | +11 | −22 | 0 |
| 3. Resultant turns......................... | + 5 | −28 | −6 |

If in the same train it were required to find the number of turns which the arm must make in order that *B* shall make −28 turns, while *A* makes +5, let $x$ be the number of turns of the arm and proceed as above.

1. With the train locked, turn the whole $x$ turns.

2. With the train unlocked, and arm fixed, turn *A* through $(-x+5)$ turns, which will cause *B* to turn $(-2)(5-x)$.

3. Add these component motions and equate the turns of *B* thus found with the given number of turns, whence $x$ may be found. Thus:

| | *A* | *B* | Arm |
|---|---|---|---|
| 1. Train locked.................................. | $x$ | $x$ | $x$ |
| 2. Train unlocked, arm fixed........................ | $-x+5$ | $(-2)(5-x)$ | 0 |
| 3. Resultant turns................................ | $+5$ | $(-2)(5-x)+x$ | $x$ |

But turns of $B = -28 = (-2)(5-x) + x$ and $x = -6$ = turns of arm.

The second method of solving these trains is by means of a general equation which applies to any epicyclic train.

$$\frac{\text{Turns of } B \text{ relative to arm}}{\text{Turns of } A \text{ relative to arm}} = \frac{\text{absolute turns of } B - \text{turns of arm}}{\text{absolute turns of } A - \text{turns of arm}}.$$

In this equation it will be seen that the first term can always be expressed in terms of the number of teeth on the gears, as it is simply the value of the train assuming the arm fixed. It is absolutely essential that this value of the train be expressed as + or −, depending on whether the gears considered turn in the same or in opposite directions relative to the arm. Thus in the previous problem,

$$\frac{\text{Relative turns } B}{\text{Relative turns } A} = -2 = \frac{\text{absolute turns } B - \text{turns arm}}{\text{absolute turns } A - \text{turns arm}} = \frac{B-(-6)}{5-(-6)},$$

where *B* in the last term represents the absolute turns of *B*; hence

$$-2 = \frac{B+6}{5+6} \quad \text{or} \quad B = -28 \text{ turns.}$$

With the data as in the second case of the first method, where $x$ represents the turns of the arm, and *B* and *A* the absolute turns of *B* and *A*, respectively,

$$-\frac{2}{1} = \frac{B - \text{arm}}{A - \text{arm}} = \frac{-28-x}{5-x},$$

$$-10 + 2x = -28 - x, \quad \text{and} \quad x = -6 \text{ turns.}$$

**FORMULAS FOR DETERMINING THE ACTION OF EPICYCLIC TRAINS.** (F. J. Bostock, *Am. Mach.*, May 16, 1907.)—See Fig. 13. **Notation.**—$R$ = driving gear or arm; $r$ = number of teeth in driving gear; $N$ = driven gear or arm; $n$ = number of teeth in driven gear or arm; $I, S, M$ = intermediate gears; $i, s, m$ = number of teeth in intermediate gears; $F$ = fixed gears; $f$ = number of teeth in the fixed gears;

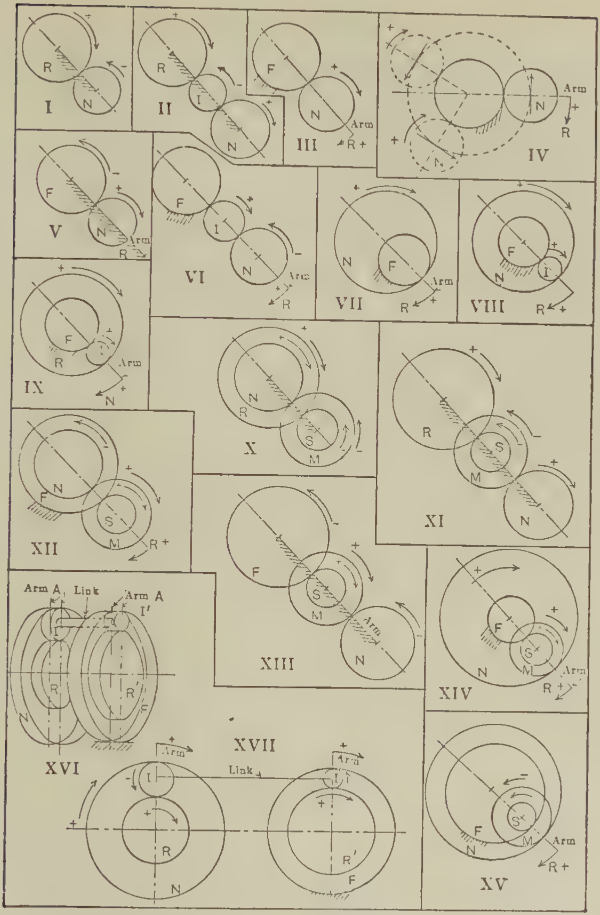

Fig. 13. Epicyclic Trains

$V_n$ = angular velocity of driven gear; $V_r$ = angular velocity of driving gear. The cross-hatching denotes that part of the apparatus that is fixed.

Formulas.—(The Roman numerals refer to the illustrations, Fig. 13.)

I. $V_n = -V_r \times (r/n)$; II. $V_n = V_r \times (r/n)$;
III. $V_n = V_r \times (1 + f/n)$; VI. $V_n = V_r \times (1 - f/n)$;
VII. $V_n = V_r \times (1 - f/n)$; VIII. $V_n = V_r \times (1 + f/n)$;
IX. $V_n = V_r \times \{r \div (r + f)\}$; X. $V_n = V_r \times (rm \div sn)$;
XII. $V_n = V_r \times \{1 - (fm \div sn)\}$; XIV. $V_n = V_r \times \{1 + (fm \div sn)\}$;
XV. $V_n = V_r \times \{1 - (fm \div sn)\}$;
XVII. $V_n = V_r \times \{(r'n - rf) \div n(r' + f)\}$.

Examples.—In Fig. 13 (III), let $f = 30$, $n = 25$; then in one revolution of $R$, $N$ will make

$$(1 + f/n) = 1 + 30/25 = 2\,{}^1/_5 \text{ revolutions.}$$

In Fig. 13 (VII), let $f = 60$, $n = 65$:

$$\frac{\text{Velocity of } N}{\text{Velocity of } R} = \frac{1 - f/n}{1} = \frac{1 - 60/65}{1} = \frac{5}{65} = \frac{1}{13}.$$

In Fig. 13 (XII), let $f = 61$, $n = 60$, $s = 40$, $m = 41$:

$$\frac{\text{Velocity of } N}{\text{Velocity of } R} = \frac{1 - (fm/sn)}{1} = \frac{1 - (61 \times 41) \div (40 \times 60)}{1} = \frac{1 - (2501/2400)}{1} = -\frac{1}{24} \text{ approx.}$$

Note that the motion of $N$ is in a negative direction.

## 7. INTERNAL GEAR DRIVES

An internal gear is one with the teeth cut into the bore instead of outside of the rim, as is the case with a spur gear. The internal gear possesses several advantages when properly applied, and is frequently used for reduction gear and planetary gear combinations. In many respects, it can be treated as a spur gear. The same basic rack forms can be used, and the mating pinion is a spur gear. The center distance on an internal gear drive is equal to the difference between the pitch radius of the internal gear and the pitch radius of the mating pinion. With an internal gear drive, both members rotate in the same direction. With its shorter center distance, the internal gear is more compact than the corresponding spur gear combination. Also, the tooth action is inherently smoother than that of a spur gear drive. The tooth forms of the internal gear are stronger than those of the corresponding spur gear; they are stronger than the basic rack tooth form. For convenience in computing their beam strength, however, it is satisfactory to use the rack tooth form factor.

When the internal gear drive is used as a reduction drive, employing a small pinion and a large internal gear, the question of design as regards the tooth shape and action does not require special consideration. It is only when the number of teeth in the pinion closely approaches the number of teeth in the gear that it is necessary to lay out the teeth to see that proper tooth action is present without interference as the teeth come out of engagement. As a general rule, the smallest permissible difference between the number of teeth in the pinion and internal gear, to avoid this interference, is 7 teeth for the stub tooth form and 12 teeth for the full depth tooth forms. Smaller differences may sometimes be used, but this requires special design of tooth forms and proportions.

Internal gears may be cut with special formed milling cutters and the use of an internal milling cutter attachment or they may be generated on a Fellows gear shaper. Such generated gears may have straight or helical teeth. See The Internal Gear, published by the Fellows Gear Shaper Company, Springfield, Vt.

## 8. STRENGTH OF SPUR GEARS

**LOAD CARRYING ABILITY OF SPUR GEARS.**—With all gear drives, there are three possible limiting factors, any one or more of which may limit the capacity of the drive. These factors are: heat of operation, beam strength of the gear teeth and surface failure, or wear of the tooth surfaces. With spur gears, heat of operation is seldom the limiting factor except when the speeds are very high or the amount of lubrication is excessive. The rate at which the heat will be dissipated from the surface of the gear case is a somewhat uncertain factor, depending largely upon the conditions of air circulation around the gear case. Under the most favorable conditions, where there is free circulation of air around the exposed surface of the case, $Q = L/35\,A$, where $Q$ = difference between room temperature and temperature of the gear case, deg. F., $L$ = power loss in ft.-lb. per min., $A$ = area of exposed surface of gear case, sq. ft. If the gear case is set in a pocket with poor circulation of air about it, then $Q = L/24\,A$. If the rise in temperature is excessive, suitable oil-cooling systems or other means of cooling should be provided.

**STRENGTH OF SPUR GEARS.**—The load carrying ability of a pair of spur gears may be limited by either the beam strength of the tooth or the surface endurance limits of the materials. The lower of these two values should be used to establish the load-carrying ability of any given drive. $W = 33{,}000\ \text{Hp.}/V$, where $W$ = transmitted pitch-line load, lb., $V$ = pitch-line velocity, ft. per min., Hp. = horsepower.

The dynamic load is the maximum momentary load set up by the operating or dynamic conditions.

$$\text{Dynamic load, } W_d = [0.05\,V(FC + W)/(0.05\,V + \sqrt{FC + W})] + W,$$

where $W_d$ = total dynamic tooth load, lb., $F$ = width of face, in., $C$ = deformation constant from Table 11.

In order to use the foregoing formula, it is necessary to have some measure of the error in action of the gears. From tests of gears made in many plants, it appears that this error on well-cut industrial gears ranges from about 0.002 in. on gears of 6-diametral pitch and finer, to about 0.004 in. on gears of 2-diametral pitch. On gears cut with particular care, these errors are reduced by about one-half the above. On ground gears made with extreme care, and on cut gears where every effort is made to secure accuracy, these errors are reduced to even smaller amounts. The foregoing conditions of error are tabulated in Table 12, and classified as Class 1, Class 2, Class 3, respectively.

Table 11.—Values of $C$*

| Materials | Tooth Form | Error in Action of Gears, in. | | | | | |
|---|---|---|---|---|---|---|---|
| | | 0.0005 | 0.001 | 0.002 | 0.003 | 0.004 | 0.005 |
| Cast iron and cast iron....... | 14 1/2° | 400 | 800 | 1600 | 2400 | 3200 | 4000 |
| Cast iron and steel.......... | 14 1/2° | 550 | 1100 | 2200 | 3300 | 4400 | 5500 |
| Steel and steel.............. | 14 1/2° | 800 | 1600 | 3200 | 4800 | 6400 | 8000 |
| Cast iron and cast iron....... | 20° f.d.† | 415 | 830 | 1660 | 2490 | 3320 | 4150 |
| Cast iron and steel.......... | 20° f.d. | 570 | 1140 | 2280 | 3420 | 4560 | 5700 |
| Steel and steel.............. | 20° f.d. | 830 | 1660 | 3320 | 4980 | 6640 | 8300 |
| Cast iron and cast iron....... | 20° sb.‡ | 430 | 860 | 1720 | 2580 | 3440 | 4300 |
| Cast iron and steel.......... | 20° sb. | 590 | 1180 | 2360 | 3540 | 4720 | 5900 |
| Steel and steel.............. | 20° sb. | 860 | 1720 | 3440 | 5160 | 6880 | 8600 |

* The values given for cast iron also are used for the ordinary semi-steels and bronze, since the modulus of elasticity of all of these materials is practically the same. † f.d. = full depth. ‡ sb. = stub.

Table 12.—Maximum Error in Action Between Gears

| Diametral Pitch | Class 1 | Class 2 | Class 3 | Diametral Pitch | Class 1 | Class 2 | Class 3 |
|---|---|---|---|---|---|---|---|
| 1 | 0.0048 in. | 0.0024 in. | 0.0012 in. | 4 | 0.0026 in. | 0.0013 in. | 0.0007 in. |
| 2 | .0040 | .0020 | .0010 | 5 | .0022 | .0011 | .0006 |
| 3 | .0032 | .0016 | .0008 | 6 and finer | .0020 | .0010 | .0005 |

As a matter of fact, noise of operation is usually a very good test of the accuracy of gears. For example, gears to run at pitch-line velocities of 5000 ft. per min. and over cannot have errors much greater than about 0.0005 in., else the noise of operation will render them unsatisfactory. Table 13 gives some measure of the accuracy required at the different velocities. This table is a guide for the selection of the proper class of gear for specific speed conditions. For extreme quietness of operation, a higher order of accuracy than shown is necessary, even at the lower speeds. The values given should keep the noise of operation and the dynamic load within reasonable limits.

Table 13.—Maximum Permissible Error in Action Between Gears

| Velocity, ft. per min. | Error, in. | Velocity, ft. per min. | Error, in. | Velocity, ft. per min. | Error, in. |
|---|---|---|---|---|---|
| 250 | 0.0037 | 1750 | 0.0017 | 3250 | 0.0009 |
| 500 | .0032 | 2000 | .0015 | 3500 | .0008 |
| 750 | .0028 | 2250 | .0014 | 4000 | .0007 |
| 1000 | .0024 | 2500 | .0012 | 4500 | .0006 |
| 1250 | .0021 | 2750 | .0011 | 5000 and over | .0005 |
| 1500 | .0019 | 3000 | .0010 | ........... | ..... |

**BEAM STRENGTH OF TEETH.**—The Lewis equation is used to determine the beam strength of the tooth. The safe static strength should not be less than the dynamic load. A margin of safety of from two to four times the applied load is desirable. Let $W_s$ = safe static load on gear teeth, lb., $p$ = circular pitch, in., $F$ = face width, in., $S$ = flexural endurance limit (stress range from zero to maximum), lb. per sq. in., $y$ = tooth form factor from Table 14. Then

$$W_s = SpFy.$$

It would appear that the flexural endurance limit of the material would be a satisfactory value to use for the limiting stress for determining the safe static load. Endurance

Table 14.—Values of $y$ in Lewis Formula

| No. of Teeth | 14 1/2° | 20° Full Depth | 20° Stub | No. of Teeth | 14 1/2° | 20° Full Depth | 20° Stub |
|---|---|---|---|---|---|---|---|
| 12 | 0.067 | 0.078 | 0.099 | 27 | 0.100 | 0.111 | 0.136 |
| 13 | .070 | .083 | .103 | 30 | .102 | .114 | .139 |
| 14 | .072 | .088 | .108 | 34 | .104 | .118 | .142 |
| 15 | .075 | .092 | .111 | 38 | .107 | .122 | .145 |
| 16 | .077 | .094 | .115 | 43 | .110 | .126 | .147 |
| 17 | .080 | .096 | .117 | 50 | .112 | .130 | .151 |
| 18 | .083 | .098 | .120 | 60 | .114 | .134 | .154 |
| 19 | .087 | .100 | .123 | 75 | .116 | .138 | .158 |
| 20 | .090 | .102 | .125 | 100 | .118 | .142 | .161 |
| 21 | .092 | .104 | .127 | 150 | .120 | .146 | .165 |
| 23 | .094 | .106 | .130 | 300 | .122 | .150 | .170 |
| 25 | .097 | .108 | .133 | Rack | .124 | .154 | .175 |

tests on steel indicate that this limit value follows quite closely the Brinell hardness number up to a stress of about 100,000 lb. per sq. in., although the structure of the material also plays an essential part. Table 15 gives suggested values to use for $S$.

**Table 15.—Values of $S$ in Lewis Formula**

| Material | Brinell Hardness No. | $S$ | Material | Brinell Hardness No. | $S$ |
|---|---|---|---|---|---|
| Gray iron......... | 160 | 12,000 | Steel............. | 280 | 70,000 |
| Semi-steel......... | 200 | 18,000 | Steel............. | 320 | 80,000 |
| Phosphor-bronze... | 100 | 24,000 | Steel............. | 360 | 90,000 |
| Steel............. | 200 | 50,000 | Steel............. | 400 and over | 100,000 |
| Steel............. | 240 | 60,000 | | | |

**LIMIT LOAD FOR WEAR.**—The limit load for wear on properly lubricated gears depends upon the surface endurance limits of the materials, the radii of curvature of the mating profiles, as well as on the hardness and structure of the surfaces of the mating teeth. A harder material in the pinion will cold-work the surfaces of a softer and malleable material of the mating gear, and thus increase its surface endurance limit materially. If $W_w$ = limiting tooth load for wear, lb. (not to be less than the dynamic load for continuous service without appreciable wear), $D$ = pitch diameter of pinion, in., $n$ = number of teeth in pinion, $N$ = number of teeth in gear, $\alpha$ = pressure angle of gears, $F$ = face width of gears, in., $Q$ = ratio factor, $K$ = load-stress factor, $E_1$, $E_2$ = moduli of elasticity of materials, $S_w$ = surface endurance limit of material, lb. per sq. in., then

$$Q = 2N/(N + n) \text{ for spur gears;}$$

$$Q = 2N/(N - n) \text{ (for internal gears);}$$

$$K = \frac{S_w{}^2 \sin \alpha}{1.40}\left(\frac{1}{E_1} + \frac{1}{E_2}\right);$$

$$W_w = DFKQ.$$

The value of $S_w$ for steel appears to vary quite consistently with its Brinell hardness numbers. The results of tests to date (1936) give, for steel, the values in Table 16.

**Table 16.—Values of $S_w$ for Steel**

| Brinell Hardness No. | $S_w$ | Brinell Hardness No. | $S_w$ | Brinell Hardness No. | $S_w$ | Brinell Hardness No. | $S_w$ |
|---|---|---|---|---|---|---|---|
| 150 | 50,000 | 300 | 110,000 | 450 | 170,000 | 550 | 210,000 |
| 200 | 70,000 | 350 | 130,000 | 500 | 190,000 | 600 | 230,000 |
| 250 | 90,000 | 400 | 150,000 | | | | |

Table 17 gives values of $K$ for various combinations of materials for 14 1/2° and 20° gears, taking into consideration the cold-working received in operation. "Cast iron" also includes the ordinary semi-steels. Some of the high-test semi-steels and other special alloys of cast iron have a greater modulus of elasticity than cast iron, and the value of $K$ for such materials must be calculated directly from their own specific properties.

**References:** Dynamic Loads on Gear Teeth, A.S.M.E. Research Publication, 1932. Am. Gear Mfrs. Assoc. Recommended Practice for Computing the Allowable Tooth Loads of Metal Spur Gears, 1932. Spur Gear Tooth Forms, B-6b-1932, Am. Stds. Assoc.

**TYPES OF PHYSICAL WEAR.**—Tests on gears and the analysis of gears badly worn in service have made apparent five distinct types of physical wear, as follows:

**Pitting,** evidenced by particles or flakes of material sheared out of the surface of the material. It is a fatigue phenomenon, and is caused by loads or pressures exceeding the surface endurance limit of the metal. The static stress conditions can be determined quite closely by the use of the Hertz equations (see p. 7–49). In operation, this problem is complicated by the tendency to plastic flow of the material. The Hertz equations for the limit load for wear apply to this type of wear only.

**Abrasion,** evidenced by the scratching or lapping of the surface of the material. It is caused by the presence of foreign matter in the lubricant, which may consist of particles of the material which have been sheared out by the pitting, or of grit picked up by the lubricant.

**Scoring,** evidenced by grooves or cuts in the surface of the material. It is caused by the projecting edges or corners of improperly finished surfaces which break through the film of lubricant and cut or score the mating surface.

Failure of the lubricant is not responsible for any of the three foregoing types of wear.

| Steel | 200 | Ph. bronze | ... | 70,000 | 87 | 119 |
| Steel | 250 and higher | Ph. bronze | ... | 85,000 | 135 | 204 |
| Cast iron | ... | Cast iron | ... | 90,000 | 193 | 284 |

Scuffing, or Galling, evidenced by dragging of the surface of the material. It is caused by the plastic flow of the surface of the material because of the failure of lubrication. This is responsible for the ridges and hollows found at the pitch line of the teeth of badly worn gears made of malleable materials, as the sliding action is towards the pitch line on the driven gear and away from it on the driving pinion.

Seizing, evidenced by the actual sticking together of two surfaces or the presence of small particles of material which have been brazed or welded to the surface. It is caused by failure of lubrication accompanied by high local heating. The action of sulphur, chlorine, etc., compounded with oils to prevent seizing is primarily that of an anti-flux to prevent this welding. The successful use of sulphur in cutting compounds is primarily due to its action as an anti-flux which prevents the building-up or welding of the material to the edge of the tool.

## 9. NON-METALLIC GEARS

In order to reduce noise and vibration in high-speed gears, one gear of the pair is often made of some non-metallic material, as rawhide, fiber or phenolic materials under various trade names, as Bakelite, Micarta, Formica, Textolite, etc.

**RAWHIDE PINIONS.**—Pinions of rawhide are in common use for gearing shafts driven by electric motors to other shafts which carry machine cut gears of cast iron or steel.

**FIBER GEARS** are used for light loads and high speeds. Fiber is comparatively inexpensive, can be purchased in convenient stock sizes, but is usually difficult to machine. In milling or cutting the teeth, better results will be secured by reversing the ordinary direction of rotation of the cutting tool.

**PHENOLIC LAMINATED GEARS** are made of a non-metallic material developed for gear requirements. It is a product of special heavy duck of uniform weave, thickness and tensile strength, bonded together with a phenolic compound by heating under pressure. This material is self-supporting and does not require metal flanges. It is also water-, moisture-, steam-, acid-, and alkali-proof.

The physical characteristics of these non-metallic materials are so different from those of metals that they should be considered in a class apart by themselves. Due to their low modulus of elasticity, most of the effects of errors are absorbed at the surface of the gear teeth and have little effect on the strength of the gears. On the other hand, the deformation under load is relatively so great that the useful load they can safely carry is limited by the tendency of the corner of the metal mating gear tooth to score the flank of the non-metallic pinion tooth because of its displacement from its theoretical position by this deformation. This scoring can be minimized by making the tooth of the non-metallic pinion all-addendum, while the tooth of the metal driving gear is all-dedendum. In such a case, about double the loads can be safely carried as compared with the safe loads on gear teeth of conventional design. The 20° stub tooth system appears to be the most effective form for use with spur gears made of these non-metallic materials, for the transmission of power. If $S$ = safe static strength of material, lb. per sq. in., $s$ = safe operating strength of material, lb. per sq. in., $p$ = circular pitch, in., $y$ = tooth-form factor (Table 14), $V$ = pitch-line velocity, ft. per min., $W$ = safe working tooth load, lb., $F$ = face width, in.,

$$s = [\{150/(200 + V)\} + 0.25]S, \quad \text{and} \quad W = spFy.$$

The safe static strength of the phenolic laminated materials is generally taken as 6000 lb. per sq. in. Values of the safe working stresses of these materials at different pitch-line velocities, $V$, are tabulated in Table 18. These values apply to gears of conventional design.

**Table 18.—Safe Working Stress for Phenolic Laminated Materials**

| $V$ | $s$ | $V$ | $s$ | $V$ | $s$ |
|---|---|---|---|---|---|
| 600 | 2625 | 1800 | 1950 | 4000 | 1714 |
| 700 | 2500 | 2000 | 1909 | 4500 | 1691 |
| 800 | 2400 | 2200 | 1875 | 5000 | 1673 |
| 900 | 2318 | 2400 | 1846 | 5500 | 1658 |
| 1000 | 2250 | 2600 | 1821 | 6000 | 1645 |
| 1200 | 2143 | 2800 | 1800 | 6500 | 1634 |
| 1400 | 2063 | 3000 | 1781 | 7000 | 1622 |
| 1600 | 2000 | 3500 | 1743 | 7500 | 1617 |

The most effective use of these materials is for high-speed duty. At low speeds, where the starting torque may be high or where the load may fluctuate widely, or when high shock loads may be encountered, the non-metallic materials do not always prove satisfactory. Hardened steel appears to be the best material to run with the phenolic laminated materials. A good second choice is cast iron or semi-steel. The use of soft steel, brass or bronze is questionable because of the tendency to excessive abrasion.

## 10. EFFICIENCY OF SPUR GEARS

In 1886, Wilfred Lewis reported the results of an extensive series of tests of the efficiency of the common types of gearing, namely, worm, spiral, and spur. In these tests, which were largely confined to worm gearing, the attempt was made to measure the efficiency of spur gears, but the apparatus was not sensitive enough for the purpose, and the errors thus introduced were relatively large. The results obtained indicated a range in efficiency of from 86 to 99% for a pair of large, carefully-cut spur gears under average conditions.

Later tests indicate that the efficiency of a pair of cut gears under average conditions is in the neighborhood of 99%, and this value proves quite satisfactory for use when computing the temperature rise of operation, etc. Recent tests indicate that the efficiency is highest with the finer pitch gears. Also, that it varies with different materials, etc. As the friction loss is so small, however, the use of the value of 1% as the power loss at the tooth-mesh proves generally satisfactory for most practical purposes.

## 11. HELICAL GEARS

Helical gears are gears whose teeth are twisted uniformly throughout the length or face of the gear. The angle, at the pitch line of the helix, of the tooth with the center-line of the gear is called the helix angle. This angle represents the angle of departure of the helix from a spur gear. The complement of this angle, or the angle between the helix and any plane of rotation of the gear, is called the lead angle. The lead of the helix is the axial distance the helix advances to make one complete revolution about the pitch cylinder.

The same basic rack forms used for spur gears are often used on helical gears. In addition, many special forms and proportions are used to meet specific conditions.

Although the conjugate action between the tooth profiles in the plane of rotation is identical to that on spur gears, there is in addition a tendency for continuous action along the helices of mating teeth. In order to obtain the full advantage of this helical action, the advance of the tooth across the face of the gear must be equal to the angular distance of one tooth-interval or more. The greater the number of teeth in helical contact across the face, the smoother will be the action because of the averaging effect of the multiple-tooth contact on the errors, etc.

Gears of this type are made with helix angles up to 45°. The larger the helix angle, the greater the number of teeth in helical contact across the face of any given gear. On the other hand, the larger the helix angle, the greater the end-thrust of the gears. The final solution in any particular case is a compromise between these conflicting factors, depending upon the nature of the drive, the facilities available for resisting end-thrust, etc. The end-thrust on the bearings may be avoided by combining two pairs of helical gears, one gear with a left-hand lead of helix and the other gear on the same shaft with a right-hand lead of helix. When the two gears are made integral from a single blank, they are called herringbone gears.

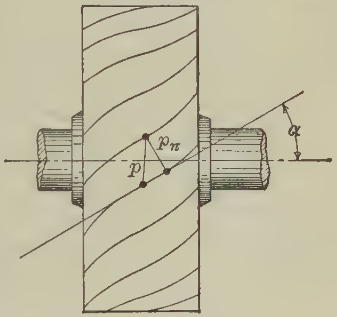

FIG. 14

**MILLED HELICAL GEARS.**—Helical gears may be produced by milling on a milling machine with the same formed milling cutters as are used for spur gears. The general formulas required for such helical gears are shown in Table 19.

**Table 19.—General Formulas for Helical Gearing**

(Adapted from Brown & Sharpe Mfg. Co., Providence, R. I.)

| To Find | Symbol | Formulas. See Fig. 14 |
|---|---|---|
| Number of teeth in gears * | $N_a, N_b$ | $N = DP_n \cos \alpha$. |
| Center distance | $C$ | $C = \frac{1}{2}(D_a + D_b) = (N_a + N_b) \div 2P_n \cos \alpha$. |
| Circular pitch (circumferential) | $p$ | $p = 3.1416\, D/N = p_n/\cos \alpha$. |
| Normal circular pitch | $p_n$ | $p_n = p \cos \alpha$. |
| Diametral pitch | $P$ | |
| Normal diametral pitch | $P_n$ | $P_n = 3.1416/p_n \cdot$(pitch of cutter). |
| Pitch diameter | $D$ | $D = pN \div 3.1416 = p_n N/3.1416 \cos \alpha = Nd \div (N + 2 \cos \alpha)$. |
| Outside diameter | $d$ | $d = D + 2a = D + (2/P_n)$. |
| Angle of teeth with axis | $\alpha$ | $\cos \alpha = N \div (P_n D)$. |
| Thickness of tooth | $t$ | $t = p_n/2$. |
| Addendum or module | $a$ | $a = p_n/3.1416 = 1/P_n = \frac{1}{2}(d - D)$. |
| Whole depth of tooth | $H$ | $H = 2a + 0.1\, t$. |
| No. of teeth marked on cutter when teeth are to be cut in milling machine † | $T$ | $T = (N/\cos^3 \alpha) + (p_n \times D_c \times \tan^2 \alpha)$ ‡ |
| Lead (exact) of spiral on pitch surface | $L_1$ | $L_1 = Np/\tan \alpha = N \times 3.1416/P \tan \alpha$. |
| Lead (approx.) of spiral on pitch surface | $L_2$ | $L_2 = 10WG_2 \div SG_1$. § |

* The subscripts $a$ and $b$ appearing in notations refer to gears $a$ and $b$.

† Cutters of composite system. See Table 4, p. 14–08.

‡ $D_c$ = diameter of milling cutter to middle of tooth profile.

§ $W$ = number of teeth on gear on worm, $G_1$, $G_2$, teeth in first and second gears on stud, respectively, $S$ = teeth in gear on screw, on spiral heads of Brown & Sharpe milling machines. The formula may not apply to spiral heads of different construction.

**HOBBED HELICAL GEARS.**—Helical gears may be hobbed, using the same hobs as are used for hobbing spur gears. There is no theoretical reason why a right-hand helical gear should not be hobbed with a left-hand hob. The use of a hob of opposite hand to that of the helical gear being cut requires the least travel of the hob into and out of the gear blank at the beginning and end of the cut. Hence if the production is large, and separate hobs are to be used for each gear of the pair, cutting time is saved by using hobs of opposite hand to the helix of the gear. For general purposes on small quantities, however, the same hob can be used for both right- and left-hand helical gears. The general formulas for these helical gears are as follows: Let $N_a$, $N_b$ = number of teeth in gears;

$C$ = center distance, in.; $p$ = circular pitch in plane of rotation, in.; $p_n$ = normal circular pitch, in.; $P$ = diametral pitch in plane of rotation; $P_n$ = diametral pitch, normal; $D$ = pitch diameter, in.; $d$ = outside diameter, in.; $\alpha$ = helix angle; $a$ = addendum, in.; $L$ = lead of helix, in. Then

$$D = N/P_n \cos\alpha; \quad d = D + 2a; \quad C = (N_a + N_b)/P_n \cos\alpha;$$
$$L = Np/\tan\alpha; \quad p = p_n/\cos\alpha; \quad P = P_n/\cos\alpha.$$

**LOAD CARRYING ABILITY OF HELICAL GEARS.**—All other factors being equal, helical gears appear to operate more smoothly and quietly than spur gears. This would indicate that the intensity of the dynamic load is less on helical gears than on spur gears. The greater possibility of multiple-tooth contact across the face of a helical gear, as compared with the contact conditions on a spur gear, undoubtedly has a large influence. The exact nature of the distribution of the load among the several teeth in simultaneous contact is still unsolved. With perfect gears and no deformation under load, it would be shared equally by all teeth in contact. With errors present, the deformation on the highest tooth must be equal to the error before another tooth can share the load. The formulas and values below appear to check conservatively with a large quantity of service data, and have been used successfully for several years.

**STRENGTH OF HELICAL GEAR TEETH.**—As with all other types of gears, the load-carrying ability of helical gears may be limited by the heat of operation, the beam strength of the teeth or the surface endurance limits of the materials. The dynamic load is the maximum momentary load set up by the operating or dynamic conditions. Where $W$ = transmitted load at pitch line, lb.; $V$ = pitch-line velocity, ft. per min.; $W_d$ = dynamic tooth load, lb.; $F$ = width of active face, in.; $C$ = deformation constant from Table 11; $\alpha$ = helix angle of gears,

$$W_d = [0.05V(W + FC\cos^2\alpha)\cos\alpha/(0.05V + \sqrt{W + FC\cos^2\alpha})] + W.$$

Helical and herringbone gears often are made with much wider faces than those commonly used on spur gears. With such wide-face gears, the load across the face is not uniform because of the torsional deformation. The following approximation will give some measure of the intensity of this load concentration at one end of the face: When $W_m$ = maximum unit dynamic load, lb. per in. of face, and $D$ = pitch diameter of pinion, in.,

$$W_m = \frac{W_d}{F}\left(1 + \frac{F}{4D}\right).$$

For herringbone gears, the value of $F$ in the above equation should be taken as the width of face of either half of the herringbone pinion because of the centering influence of the herringbone design. If the torsional deflection were uniform across the face, then the load would vary uniformly across the face, the load being greatest where the torsional deflection is least. In such a case, the average unit load would exist at the middle of the face, with a maximum and minimum unit load at opposite ends, each varying the same amount from the average. This probably is a condition that never exists because the varying load will introduce a varying torsional deflection angle. For the sake of simplicity, the foregoing approximation is based on uniform torsional deflection across the face.

**BEAM STRENGTH OF HELICAL GEAR TEETH.**—The same equations and tables as are used for calculating the beam strength of spur gears may also be used for helical gears. See pp. 14–14 to 14–17. The load conditions on helical gears are different in many respects from those on spur gears, but any error thus introduced will be on the safe side. The normal basic rack form would be used in selecting the value of $y$ from Table 14. The beam strength should be larger than the dynamic load, thus including a suitable margin of safety.

**LIMIT LOAD FOR WEAR.**—Let $D$ = pitch diameter of pinion, in.; $F$ = width of active face, in.; $K$ = load-stress factor (same as for spur gears, Table 17), $Q$ = ratio factor (same as for spur gears), $\alpha$ = helix angle, $W_w$ = limiting load for wear, lb. Then

$$W_w = DFKQ/\cos^2\alpha.$$

The limiting load for wear should not be less than the dynamic load for continuous service without appreciable wear. The types of physical wear on helical gears are identical to those on spur gears.

**NON-METALLIC HELICAL GEARS.**—The information given for spur gears of non-metallic materials may also be used for helical gears.

**EFFICIENCY OF HELICAL GEARS.**—There is some question as to the efficiency of helical gears as compared with herringbone and spur gears. Some authorities claim that herringbone gears are more efficient than spur gears, and also that herringbone gears are more efficient than helical gears because of the elimination of the end-thrust on the bearings. The amount of power loss due to end-thrust depends largely upon the efficiency of the thrust bearings. As the power loss is so small, however, the use of the value of 1% as the power loss at the tooth-mesh proves generally satisfactory for most practical purposes. For single helical gears, the power loss due to end-thrust on the bearings should be considered separately.

## 12. BEVEL GEARING

Bevel Gearing is used for connecting intersecting shafts. The teeth of bevel-gears are formed about the frustums of cones whose common vertex is the point where the shafts would meet if prolonged. These cones are called pitch-cones, since they roll upon each other and on them the teeth are pitched. When bevel-gears are the same size and the shafts are at angle of 90°, they are called *miter gears.* A *crown gear* is one in which the sides of the pitch-cone make an angle of 180° with each other. That is, the pitch-cone has no altitude and is therefore a flat surface.

**TEETH OF BEVEL-WHEELS.** (Rankine's Machinery and Millwork.)—The teeth of a bevel-wheel have acting surfaces of the conical kind, generated by the motion of a line traversing the apex of the conical pitch-surface, while a point in it is carried round the traces of the teeth upon a spherical surface described about that apex.

The operations of drawing the traces of the teeth of bevel-wheels exactly, whether by involutes or by rolling curves, are in every respect analogous to those for drawing the traces of the teeth of spur-wheels; except that in the case of bevel-wheels all those operations are to be performed on the surface of a sphere described about the apex, instead of on a plane, substituting poles for centers and great circles for straight lines. In consideration of the practical difficulty, especially in the case of large wheels, of obtaining an accurate spherical surface, and of drawing upon it when obtained, the following approximate method, proposed originally by Tredgold, is generally used:

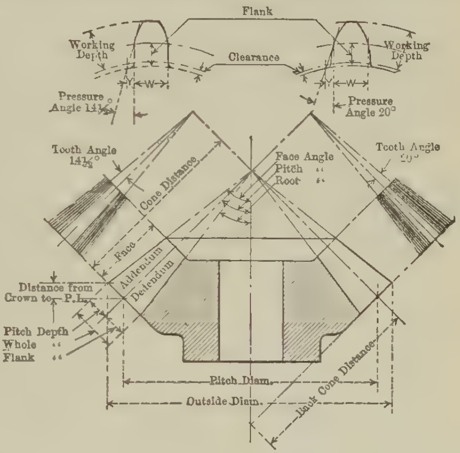

FIG. 15.—Bevel Gear Notation

Let *O*, Fig. 16, be the common apex of the pitch-cones, *OBI*, *OB′I*, of a pair of bevel-wheels; *OC*, *OC′*, the axes of those cones; *OI* their line of contact. Perpendicular to *OI* draw *AIA′*, cutting the axes in *A*, *A′*; make the outer rims of the patterns and of the wheels portions of the cones *ABI*, *A′B′I*, of which the narrow zones occupied by the teeth will be sufficiently near for practical purposes to a spherical surface described about *O*. As the cones *ABI*, *A′B′I* cut the pitch-cones at right angles in the outer pitch-circles *IB*, *IB′*, they may be called the normal cones. To find the traces of the teeth upon the normal cones, draw on a flat surface circular arcs, *ID*, *ID′*, with the radii *AI*, *A′I*; these arcs will be the development of arcs of the pitch-circles *IB*, *IB′* when the conical surfaces *ABI*, *A′B′I* are spread out flat. Describe the traces of teeth for the developed arcs as for a pair of spur-wheels, then wrap the developed arcs on the normal cones, so as to make them coincide with the pitch-circles, and trace the teeth on the conical surfaces.

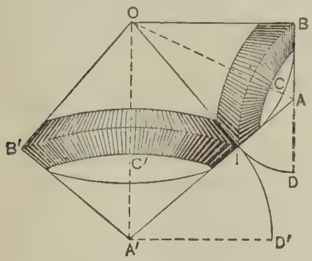

FIG. 16

For formulas and instructions for designing bevel-gears, see Practical Treatise on Gearing, and Formulas in Gearing, published by Brown & Sharpe Mfg. Co.; and Teeth of Gears, by George B. Grant. See also Rankine's Machinery and Millwork, Reuleaux's Constructor, Unwin's Elements of Machine Design, and Logue's American Machinist's Gear Book.

**FORMULAS FOR BEVEL AND ANGULAR GEARS.**—The Gleason Works, Rochester, N. Y., has published a series of rules for calculating the proportions of the various parts of bevel and angular gears. From these rules the formulas in Table 20 have been derived.

**RECOMMENDED PRACTICE FOR BEVEL GEARING.**—(Amer. Gear Mfrs. Assoc., Oct., 1919.) **Length of Face.**—The maximum length of the face of bevel gears

Table 20.—Formulas for Calculating Bevel and Angular Gears

FIG. 22. Corrected Pitch Depth, Standard and Special

should not be over 1/3 the cone distance for gears up to 3 in. pitch diameter and not over 1/4 the cone distance for gears from 3 to 20 in. pitch diameter, assuming that the pitch always is in proper proportion to the size of the gears. A safe rule is to make the face from 1 1/2 to 2 1/2 times the circular pitch.

**Length of Bearing.**—The minimum length of bearing along the face is to be at least 1/2 the length of the face when the gears are held in correct alignment. Gear users should test the strength of the gear housings as follows: Block the driven gear shaft and then apply a lever to the shaft of the driving gear and measure the displacement of both gears when a dead load is applied through the lever. This measurement can be made by inserting shims on the driving side of both ends of the teeth before and after the load is applied.

**Shape of Teeth for Bevel Gears.**—Bevel gears with generated involute teeth of standard addendum, having a pressure angle of 14 1/2 deg. may be used according to the following rule:

| Ratio | 1 to 1 | 1 1/2 to 1 | 2 to 1 | 3 to 1 and over |
|---|---|---|---|---|
| Minimum No. of Teeth | 14 | 18 | 19 | 21 |

The recommended practice rules as given are confined mainly to gears up to 20 in. pitch diameter as distinguished from larger gears. They also apply to average machine design as distinguished from gears for automobiles.

**SPIRAL BEVEL GEARS,** extensively used for driving the rear axles of automobiles, have teeth that are curved on the arc of a circle if produced by the Gleason spiral bevel-gear generator, or they are helical if produced on a generating-gear planer.

The following terms are used in referring to spiral bevel gears: *Angle of spiral* defines the angle that the line *AB* (Fig. 23), drawn tangent to the tooth at the center of the gear face, makes with the element *OA* of the pitch-cone. The *direction of spiral* refers to the direction of the spiral pinion; thus, a left-hand spiral is left-hand on the pinion and right-hand on the gear. *Lead* is the distance that the spiral advances within the face of the gear.

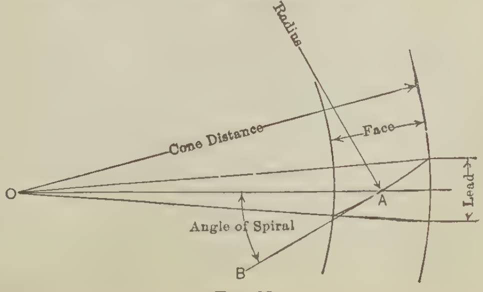

FIG. 23

For automobile practice the Gleason Works recommends gears of

4 to 5 diametral pitch and an angle of about 30°. It says that for a finer pitch, an angle of 25° to 30° will be sufficient. Although gears have been cut as low as 20° and as high as 35°, it is not advisable to go above 35°.

To obtain a sufficient lead and still keep the angle of spiral around 30°, the face may be lengthened, or, if the load is not too great, a finer pitch can be used. Either of these methods increases the amount of lead with relation to the pitch.

The teeth of spiral bevel gears wear no more than those of straight-tooth bevel gears. Due to their curvature, the teeth of spirals engage gradually and their operation is quiet. Spiral bevel pinions also permit of greater endwise adjustment than do straight-tooth bevels, and they are better adapted to high gear ratios. The load-carrying capacity of spiral-tooth bevel gears is about the same as straight-tooth bevel gears.

**END THRUST OF SPIRAL BEVEL GEARS.**—The chief disadvantage in using spiral bevel gears is the necessity of taking care of an additional end thrust on the bearings, which also may reduce the efficiency of the spiral bevel gear to slightly below that of the straight-tooth bevel gear. If the gears reverse, the thrust must be provided for in both directions. The amount of the thrust depends on several varying conditions—horsepower transmitted, pitch diameter and pitch angle of the pinion, revolutions per minute of the pinion, pressure angle and the angle of the spiral.

Where the transmitted tooth load (torque) is known, the Gleason Works gives the following approximate method for figuring the thrust: Thrust of pinion = transmitted tooth load (torque) × $C$, where $C$ is a constant, whose value is given below.

The values given for $C$ are average results from ratios between 3 to 1 and 7 to 1, and are for a pinion turning clockwise on the forward drive when viewed from the motor.

VALUES OF $C$.

| Angle of spiral................ | 20° | 25° | 30° | 35° |
|---|---|---|---|---|
| Right-hand spiral—forward..... | $C = -0.29$ | $-0.44$ | $-0.56$ | $-0.69$ |
| Right-hand spiral—reverse...... | $C = +0.41$ | $+0.59$ | $+0.72$ | $+0.85$ |
| Left-hand spiral—forward....... | $C = +0.41$ | $+0.59$ | $+0.72$ | $+0.85$ |
| Left-hand spiral—reverse....... | $C = -0.29$ | $-0.44$ | $-0.56$ | $-0.69$ |

Values with negative sign indicate pull in a direction toward the cone center; those with positive sign indicate a thrust away from the gear. The value used for transmitted tooth load or torque is to be calculated for the full pitch diameter of the pinion, not the mean diameter. The values of $C$ as given are corrected for this purpose.

EXAMPLE.—Assume 25 horsepower transmitted, 500 r.p.m. of pinion of 15 teeth, 5 diametral pitch, 3 in. pitch diameter, and 30° angle of spiral.
Transmitted tooth load $= (25 \times 33{,}000) \div \pi \times {}^3/_{12} \times 500 = 2100$ lb.
Thrust $= -0.56 \times 2100 = -1176$ lb. for right-hand spiral forward drive, and left-hand spiral reverse.
$= +0.72 \times 2100 = +1512$ lb. for left-hand spiral forward drive, and right-hand spiral reverse.

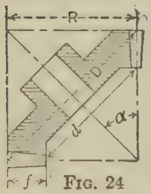

FIG. 24

**LOAD CARRYING ABILITY OF BEVEL GEARS.**—In some respects, the dynamic conditions on bevel gears are similar to those on spur gears. Because of the conical form, however, bevel gears have also many individual characteristics of their own. An axial displacement of either member of a pair from its correct position will change the contact conditions materially. Also, as the pinion usually is overhung from its bearing, bending of the pinion shaft will tend to change the contact. Bevel gears, when first set up and operated under load, seldom have complete contact across their entire face, so that the exact load conditions always are somewhat uncertain. The formulas below appear to give a reasonably close measure of the average conditions.

**STRENGTH OF BEVEL GEAR TEETH.**—The dynamic load is the maximum momentary load set up by the operating or dynamic conditions. When $W$ = transmitted load at pitch line, calculated from the pitch line velocity at the large end, lb., $V$ = pitch line velocity at large end, ft. per min., $W_d$ = dynamic tooth load, lb., $F$ = width of face, in., $C$ = deformation constant from Table 11, then,

For straight bevel gears, $W_d = [0.05\,V(W + FC)/(0.05\,V + \sqrt{W + FC})] + W$;
For spiral bevel gears, where $\alpha$ = angle of spiral,

$$W_d = [0.05\,V(W + FC\cos^2\alpha)\cos\alpha/(0.05\,V + \sqrt{W + FC\cos^2\alpha})] + W.$$

**BEAM STRENGTH OF TEETH.**—For bevel wheels Wilfred Lewis gives the following: Referring to Fig. 24, $D$ = large diameter of bevel; $d$ = small diameter of bevel; $p$ = pitch at large diameter; $n$ = actual number of teeth; $F$ = face of bevel; $N$ = formative number of teeth = $n \times$ secant $\alpha$, or the number corresponding to radius $R$; $y$ = factor depending upon shape of teeth and formative number $N$; $W$ = safe load on teeth, assumed to be applied at the large end of the bevel-gear on the pitch-line $S$ = flexural endurance limit, lb. per sq. in.

$$W = SpFy\,\frac{D^3 - d^3}{3D^2(D - d)}\;;\quad \text{or, more simply,}\quad W = SpFy\,\frac{d}{D}\;;$$

which gives almost identical results when $d$ is not less than $^2/_3\,D$, as is the case in good practice. It must be borne in mind, however, that in the case of machines which consume power intermittently, such as punching and shearing machines, the gearing should be designed with reference to the maximum load $W$, which can be brought upon the teeth at any time, and not upon the average horsepower transmitted.

Table 15 also can be used for the flexural endurance limit stresses of materials for bevel gears. The beam strength of the tooth should be enough larger than the dynamic load to give a suitable margin of safety, as in the case with spur gears.

**LIMIT LOADS FOR WEAR.**—Let $W_w$ = limiting load for wear, lb., $D$ = pitch diameter of pinion at large end, in., $F$ = face width of gear, in., $K$ = load-stress factor, Table 17, $Q$ = ratio factor, $\alpha$ = pitch angle, gear, $\beta$ = pitch angle, pinion, $N$ = number of teeth in gear, $n$ = number of teeth in pinion. Then $Q = 2N \cos\beta/(n \cos\alpha + N \cos\beta)$. For straight bevel gears, $W_w = DFKQ/\cos\beta$

For spiral bevel gears, where $\Delta$ = spiral angle,

$$W_w = DFKQ/\cos\beta \cos^2\Delta.$$

The types of physical wear on bevel gears are identical to those on spur gears.

**EFFICIENCY OF BEVEL GEARS.**—Tests on bevel gears indicate that the efficiency of well-cut and properly lubricated bevel gears ranges from about 95 to 99%. The power losses measured in these tests included the losses caused by the end thrusts, so that the design of the thrust bearings plays an important part. It is probable that the losses at the tooth-mesh alone are practically the same as for spur gears.

## 13. SCREW GEARING

Screw gearing includes those types of gears used to drive non-intersecting and non-parallel shafts, where the teeth of one or both members of the pair are of general screw form, and where the driving takes place by means of a screwing action, the sliding of the contacting tooth surfaces against each other being the predominating action. Screw gearing is of three general types: 1. Spiral gear drives; 2. Worm gear drives; 3. Hourglass or globoid worm drives. There is a fundamental difference in the nature of the geometrical construction, nature of the action and character of pitch surfaces between the three types.

**SPIRAL GEAR DRIVES.**—Helical gears used to drive non-parallel shafts commonly are known as spiral gears. In this case, both members of the pair have a uniform helical lead of tooth along their axes; each member has two pitch surfaces and also two circular pitches. One pitch surface is a cylinder; the other is a plane. The circular pitch on its pitch cylinder is the same as the circular pitch of the mating gear on its pitch plane. The circular pitch on its pitch plane equals the projection of its axial pitch along a line representing the direction of the plane of rotation of the mating gear. Thus when the two shafts are at right-angles to each other, the circular pitch on the pitch plane is equal to its axial pitch. Such pitch surfaces are shown in Fig. 25. The nature of the contact between such gears is point contact.

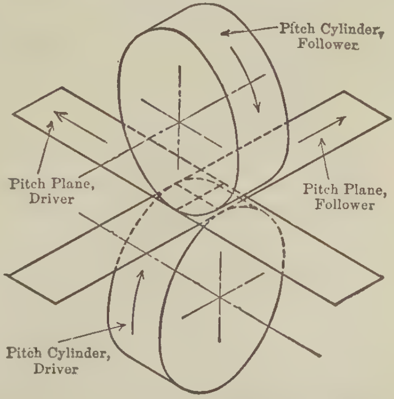

FIG. 25. Pitch Surfaces of Spiral Gears, Pitch Planes Coinciding

**WORM GEAR DRIVES.**—A common conception of a worm gear drive is that of a screw-thread driving a circular nut. A better mental image is obtained by picturing such a drive as the development of a spiral gear drive where one member has been made to envelop the other in order to obtain line contact instead of point contact. Either member may be made to envelop the other. For expediency, the more common practice has been to make the larger member envelop the smaller. Until recently, the use of a smaller member enveloping the larger one has been exceptional, and such a construction has been erroneously called an hour-glass or globoid worm drive. A worm gear drive has one member with a uniform helical lead of tooth along its axis, while the mating member is made to envelop it. The enveloping member retains its cylindrical pitch surface, but loses its pitch plane with the loss of its uniform helical lead of tooth along its axis. The helicoidal member retains its pitch plane but loses its pitch cylinder because the mating pitch plane has been eliminated. Thus the pitch surfaces of a worm drive consist of a pitch cylinder on the enveloping member and a pitch plane on the helicoidal member, and there is but one common circular pitch for both members. There can be no circular pitch in the plane of rotation of the helicoidal member unless there is a mating pitch plane with a constant axial pitch on the contacting member. The contact between the teeth of a worm gear drive is line contact.

**HOUR-GLASS OR GLOBOID WORM DRIVES.**—In an hour-glass or globoid worm drive, neither member of the pair has a uniform helical lead of tooth along its axis. One or both members may be made to envelop the other. The contact is line contact, and the pitch surfaces are indeterminate. No fixed pitch point exists. Each different design must be analyzed individually to establish the nature of the action and position of the contact. The motion is primarily that of a barrel cam operating against a series of cam followers free to rotate about an axis.

## 14. SPIRAL GEAR DRIVES

For light loads within their load-carrying capacity, spiral gears are the most satisfactory type of screw gearing. When made with reasonable accuracy, they transmit motion smoothly and quietly. This is the result of several unique characteristics of such drives. Theoretically, it is impossible to spoil the nature of the action by mislocation or misalignment. As ordinarily designed, the pitch planes of mating gears coincide but travel in different directions (see Fig. 25), depending on the direction of the planes of rotation of the two helical gears. If the axes of the gears are moved farther apart, the sizes of the pitch cylinders will remain unchanged, the corresponding pitch planes will remain tangent to their respective pitch cylinders, and will not coincide. (See Fig. 26.) The conjugate action between the tooth profiles, however, would remain theoretically correct. The gears could be so designed that the axes would be shifted to bring the entire tooth profiles between the two pitch planes, the only result being a relatively small reduction in the duration of contact.

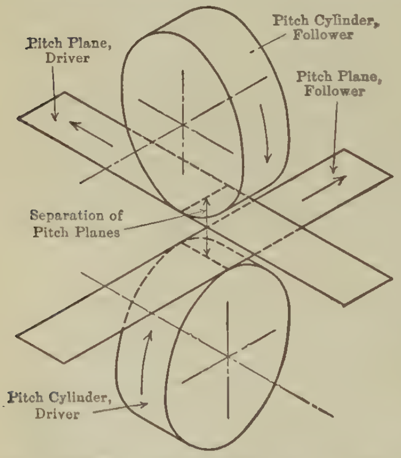

Fig. 26. Pitch Surface of Spiral Gears, Pitch Planes Separated

A similar shifting of the pitch surfaces will occur if the angular setting of the axes of the gears be changed. The circular pitches on the pitch planes then would change, as these pitches depend on the direction of the plane of rotation of the mating gear in relation to their axial position, and this also would cause the size of the mating pitch cylinder to change accordingly. The results of these characteristics are that errors in the position or alignment of involute helical gears used as a spiral gear drive have no effect on the correctness of tooth action.

Generally, the helix angles on a pair of spiral gears are of the same hand. If the angle between shafts is small, however, the helix angles may be of opposite hand. Except when both helix angles are the same, there is no direct solution for the helix angles and pitch diameters of spiral gears, unless the center distance may be varied to suit the particular combination of helix angles which are selected arbitrarily. The final result in all other cases must be found by trial. When spiral gears have helix angles of the same hand, the one with the greater helix, or lesser lead, angle always should be the driver. Except with gears of the same helix angle, the diameters of spiral gears are not directly proportional to the numbers of teeth. The speed ratio is established by the numbers of teeth and not from the diameters. Also the terms *driver* and *follower* are commonly used for spiral gears in place of the terms *pinion* and *gear*.

Let $C$ = center-distance, in., $P_n$ = normal diametral pitch (or diametral pitch of basic rack), $n$ = number of teeth in driver, $N$ = number of teeth in follower, $\alpha$ = helix angle of driver, $\beta$ = helix angle of follower, $\gamma$ = angle of axes, $d$ = pitch diameter of driver, in., $D$ = pitch diameter of follower, in. Then $d = n/P_n \cos\alpha$, and $D = N/P_n \cos\beta$.

When the two pitch planes coincide, $2C = d + D$.

When both helix angles are of the same hand, $\gamma = \alpha + \beta$.

When the helix angles are of opposite hand, $\gamma$ = difference between $\alpha$ and $\beta$.

When $L_1$ = lead of driver, in., and $L_2$ = lead of follower, in., $L_1 = 3.1416\, d/\tan\alpha$; $L_2 = 3.1416\, D/\tan\beta$.

The foregoing equations give all of the basic relationships required to solve any spiral gear problem. As noted before, in many cases the mathematical solution is indeterminate and must be solved by trial. The following simple graphical solution has been devised by J. K. Olsen, chief-draftsman of the Stewart-Warner Speedometer Corp.:

Referring to Fig. 27, the number of teeth and normal diametral pitch are selected arbitrarily. Circles are drawn representing the pitch diameters of the corresponding spur gears at the required center-distance. Two intersecting straight lines are drawn on tracing paper, the angle between them corresponding to the angle between the shafts. This tracing is then placed over the two drawn circles and adjusted until both lines are tangent to their respective circles. Their intersection is on the common center line of the two circles. The respective distances from the centers of the driver and follower to the intersection of the two lines on the common center line are the pitch radii of driver and follower. The angle between the vertical center line of each circle and the line tangent to that circle is the helix angle of that member. The values of the helix angle and pitch radii would be measured from the layout, and should be checked by the above equations. If the sum of the two pitch diameters so calculated is less than twice the specified center-distance by not more than the depth of the tooth, no further refinement is necessary. The leads should be calculated from the formulas, using the measured values of the helix angles and the calculated values of the pitch diameters. The outside diameters of the gear blanks then would be so chosen that their sum equals twice the center-distance plus twice the working depth of the tooth of the gear system used. The teeth would be cut to the standard depth in these blanks. The exact position of the tooth form in relation to the pitch cylinders is of little importance.

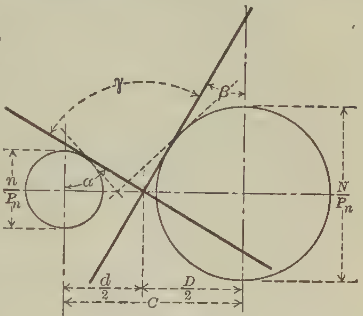

FIG. 27

Fig. 27 applies to the conditions when the two helix angles are of the same hand. In most cases, two points will be found on the common center line which meet the foregoing requirements. The point which gives the larger pitch radius and helix angle to the driver should be used. Sometimes the initial selection of tooth-numbers and pitch results either in a condition where the intersection of the two lines on the tracing paper cannot touch the common center line, or the diameters so obtained are not satisfactory. In the first case, a new selection should be made which will reduce the size of the original circles. In the second case, a new selection should be made in which the size of the circles will be increased.

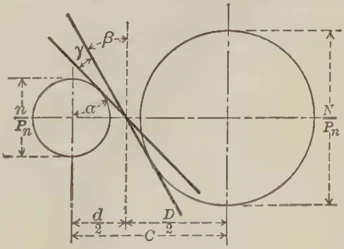

FIG. 28

When the angle between the shafts is small, and the helix angles are to be of opposite hand, the procedure is as indicated in Fig. 28. The procedure is the same as before, except that one line must be tangent to one circle *above* the common center line, while the other line must be tangent to the second circle *below* the common center line.

**TOOTH FORMS FOR SPIRAL GEARS.**—Either the 14 1/2-deg. composite system for milled gears, or the 14 1/2-deg. full depth involute system for generated gears, give the most satisfactory tooth forms for spiral gear drives. The selection of the proper milling cutter, etc., for milled spiral gears is identical to that for helical gears as shown in Table 19.

**LOAD CARRYING ABILITY OF SPIRAL GEARS.**—The nature of the contact between spiral gears is point contact. Because of this point contact, relatively light tooth loads set up very high compressive stresses in the material at the point of contact. With spiral gears, excessive wear due to pitting or abrasion is usually the most critical condition to be avoided, as the teeth will wear excessively under much smaller loads than those required to break the teeth.

Practically no reliable information is available as to the safe loads for wear on spiral gears. The limit load for wear on such gears is very uncertain. If the gears are operated in their actual working position under a light load for a period of time until a thin polished line or band appears on the teeth where contact occurs, they can then carry appreciably greater loads without excessive wear than they could if assembled and operated under full load without the preliminary polishing run. Again, if the gears are carefully run in under increasing loads until a polished band of appreciable width appears on the surfaces of the gear teeth where contact takes place, they can then carry very much higher loads without excessive wear than they can carry after only a short polishing run. In fact, the longer a pair of spiral gears run without abrasive wear on the tooth surfaces, the greater will be the loads that they can carry without excessive wear. It should be apparent, therefore, that load factors given for spiral gears depend on the care with which they have been run in after their installation. With proper care, a load that would cause excessive wear on the gears when first assembled may often be increased to several times the original limit load, because of the influence of careful running in, without resulting in appreciable wear. On the other hand, when excessive abrasive wear has once started, it is almost impossible to stop it without shifting the position of the gears and thus bringing a new part of the tooth surface into contact.

The following formulas and load factors have proved to be reasonably reliable in practice. These are based on initial running in as indicated. The relationship of the dynamic load to the transmitted load is still an open question. In general, because of the screwing action of spiral gear teeth, their operation is much smoother than that of spur or bevel gears. In the absence of definite information, the following relationship may be used: Let $W$ = transmitted tooth load, lb., $W_d$ = dynamic tooth load, lb., $V$ = pitch line velocity of follower in plane of rotation, ft. per min., $d$ = pitch diameter of driver, in., $D$ = pitch diameter of follower, in., $K$ = load factor, Table 21, $Q$ = ratio factor. Then,

$$W_d = \{(1200 + V)/1200\}\, W;\quad Q = \{(2 \times D)/(d + D)\}^2$$

$$W_w = d^2KQ, \text{ where } W_w = \text{limit load for wear, lb.}$$

**Table 21.—Values of *K* for Spiral Gears**

| Materials in Gears | After Short Polishing Run | After Careful Polishing Run |
|---|---|---|
| Steel and steel (250 Brinell) | 2 | 5 |
| Steel (250 Brinell) and bronze | 4 | 12 |
| Steel (500 Brinell) and bronze | 5 | 20 |
| Steel (500 Brinell) and cast iron | 6 | 20 |
| Steel (500 Brinell) and steel (500 Brinell) | 7 | 15 |
| Cast iron and cast iron | 8 | 20 |
| Non-metallic and steel or cast iron | 10 | 25 |

In general, to avoid sparking, bronze or non-metallic materials or hardened steel should be used when the pitch line velocity of either member in their plane of rotation is much in excess of 1000 ft. per min. Bronze never should be used in combination with the non-metallic materials for spiral gears, because of the excessive abrasion or lapping that takes place on the bronze member. In Table 21, semi-steel may be substituted for cast iron when desired.

## 15. WORM GEAR DRIVES

A worm gear drive consists of two members: 1. A helicoidal member with a uniform axial lead; 2. A member partially enveloping the helicoidal member. That is, a worm gear drive is a development of the spiral gear drive, where one member has been made to envelop the other to obtain line, instead of point, contact between the mating tooth surfaces. In most cases, worm drives are used to drive shafts at 90° to each other. They can be substituted, however, for any spiral gear drive, regardless of the angle between the shafts.

The pitch surfaces consist of a pitch plane on the helicoidal member and a pitch cylinder on the enveloping member. The conjugate tooth action best can be studied as a special case of a rack and a gear. The same conjugate tooth action exists when the helicoidal member is moved, without revolving, in an axial direction as exists when the helicoidal member revolves. The rack form, however, is not constant across the face of the enveloping member, but is of changing form. (See Fig. 29.) The amount of change in form depends upon the thread angle in the axial section, the lead of the helicoid and its diameter, and the distance of the particular section from the axial plane. Because of these conditions, higher thread angles are required for effective tooth action as the lead angle is increased. Narrower faces for the enveloping member are sometimes desirable for the higher lead angles, particularly if the thread angle in the axial section is relatively small. Thus a 14 1/2-deg. thread angle should not be used for lead angles greater than about 15 deg.; a 20-deg. thread angle should not be used for lead angles greater than about 25-deg.; a 25-deg. thread angle should not be used for lead angles greater than about 35 deg.; while a 30-deg. thread angle is desirable for lead angles up to 45 deg.

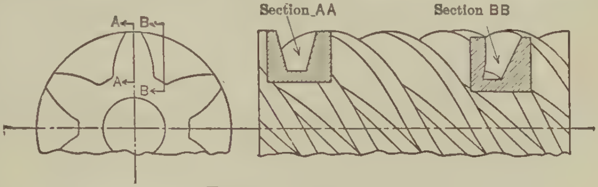

Fig. 29. Worm Gear

Many types of helicoids are used for worms. Where the lead angle is small, the actual forms produced by different methods of cutting the thread are similar, although they are different types of helicoids. As the lead angles increase, however, marked differences become apparent. For example, the axial form of the thread profile produced by a straight-sided lathe tool, tipped to the lead angle, is concave. That produced by a straight-sided milling cutter set to the lead angle generally is convex; although in extreme cases where the diameter of the cutter is small in relation to the depth of the thread and the lead angle is large, the axial form may be of double curvature, convex near the root and concave near the outside or tip of the thread. The larger the diameter of the cutter, the greater the amount of curvature in the axial profile of the thread, because of the side-cutting action of the cutter. If the milling cutter axis is parallel to the axis of the helicoid or worm, a condition that exists when hobbing a thread with an annular cutter, the form produced is that of an involute helicoid which is that of an involute helical gear. This same involute helicoid also is produced when the flat side of a cutter or grinding wheel, set to both the thread angle and lead angle, is used. Fig. 30 shows the differences in axial profile produced on a worm with a lead angle of nearly 45 deg. by different tools of the same form of cutting edge. These tools include a straight-sided threading tool set to the lead angle, a 4-in. diameter milling cutter, a 12-in. diameter grinding wheel, and the involute helicoid which would be produced by the flat side of a milling cutter or grinding wheel.

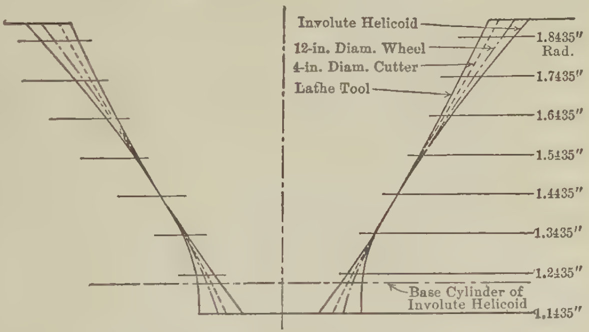

Fig. 30. Axial Sections of Milled and Chased Worms

All of these forms of helicoids have been commonly used as thread forms for worms. As far as theoretical conditions are involved, one type does not appear to have any great inherent advantage over another. The major consideration is that the same form of helicoid as is used for the worm should be reproduced on the cutting tool which is to be used to generate the enveloping member. In general, the best form to use is largely a matter of expediency, controlled by the type of equipment available to produce the helicoidal member. Hence the tool-maker must know the method to be used to produce the helicoidal member in order to make correctly the cutting tool which is to be used to generate the enveloping member.

For many practical reasons, the involute helicoid would appear to be the best form to use where the design is not restricted by existing equipment. With this helicoid, the same hob or generating cutter which is used to generate the enveloping member also may be used to generate the worm or helicoidal member. Again, with this helicoid, the helicoidal members would be involute helical gears, and the same hob or other generating cutter could be used to generate all worms of the same normal diametral pitch of all tooth-numbers. Under such conditions, the practice and technique already developed in the making of tools for helical and spur gears could be applied directly to the making of tools for worms and worm gears. Furthermore, this involute helicoidal form, where ground worms are required, is the simplest one to grind and control, the size of the wheel has no influence on the form produced, and several different grinding methods are available.

In the further discussion, the angle of the thread form will refer to the tangent to the thread profile at or near the middle of the working depth, regardless of the type of helicoid involved.

Fig. 31. Contact Lines and Field of Contact

**CONTACT ON WORM GEAR DRIVES.**—The analysis of worm drives is a very complex operation. In the majority of cases, where such analyses have been made, only the conjugate action between parallel sections of the worm, treating them as rack sections, meshing with the enveloping member or gear, have been considered. In addition, it is necessary to have some measure of the nature and position of the actual contact lines between mating teeth, duration and field of contact between them, in order to determine even approximately the intensity of the stresses and probable load-carrying capacities of such drives. Fortunately all types of helicoids follow certain general laws so that workable approximations are possible in all except the extremely critical conditions.

Considerable uncertainty exists as to the most effective position of the pitch plane in relation to the tooth on the worm. The conventional design places it at the middle of the working depth of the tooth or thread on the worm. The practice in some plants is to place it nearer the root of the thread. On all types of helicoids, the tendency of the contact lines is to converge towards the pitch line on the leaving side of the worm. (See Fig. 31.) This shows a 6-thread worm with straight sides of thread in an axial section, meshing with a 40-tooth gear. The heavy outline on the plan view of the worm shows the projection of the field of contact. In the relative position of the two members as shown, contact exists on three threads of the worm as shown by heavy lines *A*, *B*, and *C*.

Using this same worm, when the pitch line is dropped to the outside diameter of the gear, by simply closing in the center distance the amount that the pitch plane is moved, the contact conditions are as shown in Fig. 32. Here the contact lines tend more to sweep from the bottom to the top of the worm thread. This change in position of the contact lines causes much lower stresses to be set up in the materials by the same applied load, as compared with the conditions in Fig. 31. Because of the relative curvature conditions at the contact lines the drive, Fig. 32, can safely carry about double the loads that the drive, Fig. 31, can carry, even with a portion of the gear face undercut as shown. With lower lead angles, the change is less with a change in the position of the pitch plane.

In the design of a worm drive, the center distance can be varied a limited amount, and the pitch plane may be placed anywhere between the middle of the working depth of the thread on the worm and the outside diameter of the gear to suit other conditions, such as a prefixed center distance. On the other hand, the lower the pitch plane is placed on the worm thread, the greater will be its load-carrying capacity and the smoother the action.

**DESIGN OF WORMS.**—Considerable difference of opinion exists as to whether the form of the thread in the axial section or that in the so-called "normal section" should be specified. As a matter of fact, there is no "normal section" as generally implied on any helicoid. As noted before, the essential information is best specified by stating the shape, type and size of the tool to be used to finish the worm. The Am. Gear Mfrs. Assoc. recommends that the thread form to be regarded as standard will be the form produced by a straight-sided milling cutter having a diameter not less than the outside diameter, nor greater than $1\frac{1}{4}$ times the outside diameter, of the worm; also, that the following linear pitches be regarded as standard: $\frac{1}{4}$, $\frac{5}{16}$, $\frac{3}{8}$, $\frac{1}{2}$, $\frac{5}{8}$, $\frac{3}{4}$, 1, $1\frac{1}{4}$, $1\frac{1}{2}$, $1\frac{3}{4}$, 2 in.

Since the pitch surface of the worm or helicoidal member is a plane, and since the pitch on such a plane is constant at all distances from the axis, the term *pitch diameter of a worm* is misleading. Considering it as on a screw-thread, where the same term is used to define that diameter where the thread thickness is equal to the width of space, or where both distances are equal to one-half the pitch, it might best be called the nominal pitch diameter, or better, the effective diameter.

FIG. 32. Contact Lines and Field of Contact

The Am. Gear Mfrs. Assoc. also recommends that the top edge of the worm thread should always be rounded to avoid cutting, and that the amount of this rounding be made equivalent to 0.05 linear pitch. When the pitch plane of the worm is dropped to about its root diameter or lower, and the worm is the driving member, the conjugate tooth action at this edge always is recess action and under such conditions this rounding is not necessary.

The Am. Gear Mfrs. Assoc. recommends the use of a $14\frac{1}{2}$-deg. and a 20-deg. thread angle for worms from single to quadruple threads. As noted before, the lead angle and not the number of threads is the major factor that should determine the selection of the thread angle. To these two angles could be added a 25-deg. and a 30-deg. thread angle to cover all lead angles up to 45 deg. or higher. If a single thread angle is to be used, the 30-deg. thread angle can be effectively used on the lower lead angles, and several manufacturers of worm gears have adopted this angle as standard for all worms, with very satisfactory results.

**MILLED AND CHASED WORMS.**—For milled and chased worms, where definite axial pitches are maintained, a choice between two procedures is necessary: 1. If fixed tooth heights are used for the same pitch, regardless of the lead angle, a different cutter will be required for each different lead angle. 2. If the same milling cutter or chasing tool is to be used for all worms of the same axial pitch, regardless of the lead angle, a different tooth height must be calculated for each lead angle. In general, as regards the standardization of gears, greatest benefits and economies will be secured by standardizing the tools used to produce them, together with the reduction of variety as far as possible. The use of a single cutter for all worms of a given pitch evidently would be the most economical procedure. In such a case, let $p$ = axial pitch of worm, in., $\alpha$ = half included angle of cutter, $\beta$ = lead angle of worm, $L$ = lead of worm, in., $f$ = width of flat at tip of cutter, in., $c$ = clearance, in., $D$ = nominal pitch diameter of worm, in., $a$ = nominal

addendum, in., $W$ = working depth of thread, in., $H$ = whole depth of thread, in., $d$ = outside diameter of worm, in., $r$ = root diameter of worm, in.
Then, when $c = a/6$,

$$W = \{3/(7 \times \tan\alpha)\}(p\cos\beta - 2f);\ a = W/2 = \{3/(14\tan\alpha)\}(p\cos\beta - 2f);$$

$$H = W + c = 13\,W/12.$$

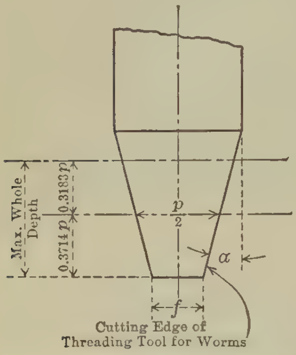

FIG. 33. Forms of Threading Cutters

Fig. 33 and Table 22 show satisfactory forms for threading cutters of the several thread angles.

For worms which are to be made integral with the shaft, for lead angles less than 45 deg., and where a shank hob is used to generate the gear, the formula, $D = 2p + 0.5$, may be used. The Am. Gear Mfrs. Assoc. recommends for worms which are to be mounted on the shaft, $D = 2.4\,p + 1.1$. In both cases, $d = D + W$; $\tan\beta = L/3.1416\,D$; $r = d - 2H$.

**HOBBED WORMS.**—With the increasing use of multiple-threaded worms, where the number of threads on the worm may be 24 or more, the hobbing of worms is growing in favor. In this case, there is no reason why the standard spur and helical gear hobs should not be used to produce such worms, where lead angles are low. For higher lead angles, involute gear hobs with a pressure angle of 30 deg. would prove effective. The form of the basic rack could be the same as shown for the form of the 30-deg. threading tool in Fig. 33. The sizes of such worms would be computed exactly the same as for helical gears, and the generating tool for the worm gear should be made to suit the worm thread form.

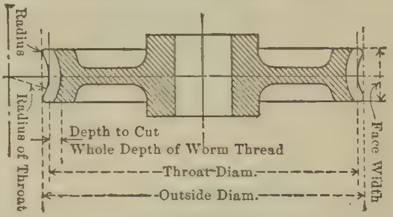

FIG. 34. Worm Gear

**DESIGN OF WORM GEARS.**—The pitch diameter of the worm gear depends on the number of teeth in the gear and the axial pitch of the worm. Let $D_g$ = pitch diameter of worm gear, in.; $N$ = number of teeth in gear; $p$ = circular pitch (axial pitch of worm), in. Then $D_g = pN/3.1416$. All other dimensions of the worm gear depend primarily upon the size of the worm and the center distance. Referring to Fig. 34, when $D$ = nominal pitch diameter of worm, in.; $r$ = root diameter of worm, in.; $c$ = clearance, in.; $W$ = working depth of worm thread, in.; $C$ = center distance, in.,

$$\text{Throat diameter} = 2C - (r + 2c);$$

$$\text{Throat radius} = (r/2) + c;$$

$$\text{Outside diameter} = \text{throat diameter} + (W/2).$$

Face width varies from 0.70 $D$ to 0.50 $D$, depending on the rubbing speed of the worm. With increasing rubbing speeds, the face diameter should be reduced. The pitch diameter of the worm gear should lie between the diameter equal to $(2C - D)$ and the outside diameter of the worm gear. As noted before, the lower the pitch plane is placed on the worm thread, the greater is the load-carrying capacity and the smoothness of the action.

Table 22.—Dimensions of Threading Cutters (See Fig. 33).

| Thread Angle, α | 14 1/2° | 20° | 25° | 30° |
|---|---|---|---|---|
| Tan α | 0.25862 | 0.36397 | 0.46631 | 0.57735 |
| Maximum whole depth | 0.6897$p$ | 0.6897$p$ | 0.6897$p$ | 0.6897$p$ |
| Maximum lead angle, β | 15° | 25° | 35° | 45° |
| Width of flat, $f$ | 0.3079$p$ | 0.2297$p$ | 0.1537$p$ | 0.0712$p$ |
| $2f$ | 0.6158$p$ | 0.4594$p$ | 0.3074$p$ | 0.1424$p$ |
| $3/(14\tan\alpha)$ | 0.82857 | 0.58875 | 0.45953 | 0.37115 |

In general, the pitches commonly used on worm drives are much coarser than are required. The multiple threaded and finer pitch worms are more efficient and run more smoothly than coarser pitch worms. To obtain the most effective worm drive, the pitch should be as fine as the strength of the gear teeth permit. For effective tooth action and full contact across the face of the worm gear, the sum of the number of teeth in the worm and worm gear should be not less than about forty.

**HOBS FOR WORM GEARS.**—The hob for a worm gear should be substantially a duplicate of the mating worm, but two precautions must be observed: 1. The nominal pitch diameter of the hob never must be less than that of the mating worm. If the hob is smaller, contact will be concentrated on the edges of the face of the worm gear, with attendant cutting or scoring and rapid wear. The amount which the hob can be made oversize depends largely on the lead angle of the worm. With low lead angles, it can be made appreciably larger, but with the high lead angles, it can be made only a very small amount oversize, unless the axis of the hob is to be twisted slightly in relation to the normal position of the axis of the worm. Such twisting will throw the initial contact towards the center of the worm face. 2. The length of the hob never should be less than the length of the mating worm in order to fully generate the contacting surfaces. This applies particularly to cases where relatively short worms are used. In general, a hob whose length is equal to 6 or 7 times the axial pitch of the worm will be sufficiently long for all purposes. If shorter hobs are used, the worm should be made somewhat shorter than the hob. If a differential feed of the hob across the periphery of the worm gear is used, shorter hobs are satisfactory, and such hobs often are made as tapered hobs, thus combining the roughing and finishing operation. In such cases, the length of the full diameter of the hob plus the distance of differential feed should be slightly greater than the length of the mating worm.

**LOAD-CARRYING CAPACITY OF WORM DRIVES.**—As with all other types of gearing, there are three limiting factors, any one or more of which may limit the capacity of the drive. These factors are: heat of operation, beam strength of teeth, and surface endurance limits of materials. With worm drives, heat of operation and the surface endurance limits of the materials are the principal limiting factors.

On worm drives, rubbing velocity and pitch line velocity must be considered. For simplicity, consider rubbing velocity to be equal to peripheral velocity at the nominal pitch diameter of the worm, although it varies at different points and may be greater or less than that used, depending upon the nature of the contact. Whence,

$$\text{Rubbing velocity in ft. per min.} = 0.2618\,D \times \text{r.p.m.},$$

where $D$ = nominal pitch diameter of worm, in., r.p.m. = rev. per min. of worm.

$$V = (L \times \text{r.p.m.})/12,$$

where $V$ = pitch line velocity of worm gear, ft. per min., and $L$ = lead of worm, in.

The actual intensity of the dynamic load on worm gear teeth is an open question. In the absence of more definite information, the following relation may be used: $W$ = transmitted tooth load, lb., $W_d$ = dynamic tooth load, lb. Then

$$W_d = W\{(1200 + V)/1200\} \text{ for metal gears}$$
$$= W\{(200 + V)/(200 + 0.25\,V)\}, \text{ for phenolic laminated material.}$$

**BEAM STRENGTH OF WORM GEAR TEETH.**—The Lewis equation may be used to determine the beam strength of worm gear teeth. The safe static strength should be not less than the dynamic load. Let $W_s$ = safe static tooth load, lb., $p$ = axial pitch of worm, in., $F$ = face width of worm gear, in., $S$ = flexural endurance limit of material, lb. per sq. in., $y$ = tooth-form factor; then

$$W_s = SpFy.$$

For steady loads $W_s$ should be about 1.25 $W_d$; for shock loads, $W_s$ should be about 1.50 $W_d$.

With the changing forms and heights of the worm gear teeth across the face, an exact tooth-form factor is a difficult value to obtain. For all practical purposes, where the sum of the number of teeth in the worm and worm gear is not less than 40, a constant value of $y$ for each thread angle can be used, as follows:

| Thread angle = | $14\,^1/_2$ deg. | 20 deg. | 25 deg. | 30 deg. |
|---|---|---|---|---|
| $y$ = | 0.100 | 0.125 | 0.150 | 0.175 |

A hobbed worm gear never is generated completely. Its final finishing is obtained by its actual operation in position with its mating worm. For this reason, the materials used for worm gears should be such that they will conform to the worm without galling or excessive abrasion. Furthermore, the material of the worm should be smooth and hard enough to retain its form through such running-in or burnishing. Therefore, a steel worm to transmit power should have a Brinell hardness of not less than 250, and be as much harder as practicable.

Cast iron and semi-steel, manganese-, phosphor-, and some nickel-bronzes, and several of the aluminum alloys have proved to be satisfactory materials for worm gears, while the phenolic laminated materials prove very effective for the smaller gears and high-speed applications. Cast iron or semi-steel should not be used for rubbing velocities greater than about 1000 ft. per min. because of the danger of sparking. High-grade bronzes and aluminum alloys are essential for satisfactory results. A poorly alloyed material is practically worthless for a worm gear material. Values for $S$ are given in Table 23.

**Table 23.—Values of $S$ for Worm Gears**

| Material | $S$ | Material | $S$ |
|---|---|---|---|
| Gray iron | 12,000 | Manganese-bronze | 17,000 |
| Semi-steel | 18,000 | Phosphor-bronze | 24,000 |
| Phenolic laminated material | 6,000 | | |

Values for nickel-bronze and for the various alloys of aluminum suitable for worm gear materials should be obtained from the manufacturers of the materials. See also pp. 4–19 to 4–33. It should be appreciated that increased physical strength obtained at the expense of lesser ductility of the material is of questionable advantage in materials to be used for worm gears. Also, the physical properties and structure of these materials depend more on the care and skill with which they have been alloyed, poured and heat treated than upon the chemical analysis alone. Alloys of the same chemical analysis may have strength and wear values varying as much as two to one because of the difference in making and the difference in the resulting structure.

**LIMIT LOADS FOR WEAR.**—Let $W_w$ = limiting load for wear, lb.; $D_g$ = pitch diameter of worm gear, in.; $F$ = face width of worm gear, in.; $K$ = load-stress value, Table 24; then,

$$W_w = D_g FK.$$

The values of $W_w$ should not be less than the dynamic load.

**Table 24.—Values of $K$ for Worm Gears**

Running with steel worms of 250 Brinell or higher

| Material in Worm Gear | $K$ | Material in Worm Gear | $K$ |
|---|---|---|---|
| Cast iron or semi-steel | 50 | Phosphor-bronze | 100 |
| Manganese-bronze | 80 | Phenolic laminated material | 125 |

**EFFICIENCY OF WORM GEAR DRIVES** depends on several factors, *viz.*, the lead angle of the worm, the nature of the contact, intensity of the load, speed of rubbing, etc. When $E$ = efficiency; $\beta$ = lead angle of worm; $f$ = coefficient of friction,

$$E = \{\tan \beta(1 - f \tan \beta)\}/(\tan \beta + f).$$

This applies to the efficiency at the tooth mesh only. The overall efficiency of a complete drive also must include the power losses of the thrust and radial bearings of both members of the drive.

The coefficient of friction will vary with the rubbing speed and with the load, and follows closely the conditions existing on plain cylindrical bearings, except that the unit loads on worm gear drives are much greater than those on plain bearings. The values in Table 25 represent average conditions. Table 26 shows the pronounced influence of the lead angle of the worm on the efficiency of the drive. These values are calculated from the foregoing equation, using the values of $f$ given in Table 25.

**Table 25.—Values of the Coefficient of Friction $f$ in Worm Drives**

| Rubbing Speed, ft. per min. | $f$ | Rubbing Speed, ft. per min. | $f$ | Rubbing Speed, ft. per min. | $f$ |
|---|---|---|---|---|---|
| 5 | 0.146 | 150 | 0.045 | 1000 | 0.041 |
| 10 | .116 | 200 | .042 | 1250 | .046 |
| 20 | .090 | 300 | .040 | 1500 | .050 |
| 40 | .070 | 400 | .036 | 1750 | .054 |
| 80 | .054 | 500 | .033 | 2000 | .058 |
| 100 | .050 | 750 | .036 | 2500 | .065 |

A worm with a lead angle of 30 deg. is practically as efficient as one with 45 deg. Lead angles less than 10 deg. are very inefficient.

The heat of operation of worm gear drives would be estimated in the same manner as shown for spur gears, by determining values for the power loss in ft.-lb. per min., and the exposed area of the case in sq. ft.

**Table 26.—Relation of Lead Angle, Speed, and Efficiency of Worm Gear Drives**

| Rubbing Velocity, ft. per min. | Lead Angle of Worm 5° | 10° | 15° | 25° | 35° | 45° |
|---|---|---|---|---|---|---|
| | Efficiency | | | | | |
| 5 | 0.37 | 0.53 | 0.62 | 0.71 | 0.74 | 0.75 |
| 10 | .42 | .59 | .68 | .76 | .79 | .79 |
| 20 | .49 | .65 | .73 | .80 | .83 | .83 |
| 40 | .55 | .71 | .78 | .84 | .86 | .87 |
| 80 | .61 | .76 | .82 | .87 | .89 | .90 |

**HOUR-GLASS WORM DRIVES.**—Hour-glass or globoid worm drives are those where neither member of the pair has a uniform helical lead along its axis. The earliest type of such a drive is the Hindley worm. Many other drives of this type since have been designed. Each different drive of this type has so many individual features that they require individual analyses to determine the exact nature of the contact, etc. Also their production requires special manufacturing facilities. In all cases, however, the maximum theoretical contact that can be obtained is line contact.

## 16. MATERIALS OF GEARS

**MATERIAL FOR BRASS AND BRONZE GEARS.**—(Recommended Practice of the Amer. Gear Mfrs. Assoc., 1933.)—**Spur and Bevel Gears.**—Hard cast bronze, S.A.E. Specification No. 62 is recommended. The following are the limits of composition:

Copper, 86 to 89%; tin, 11 to 9%; zinc, 3 to 1%; lead, max., 0.20%; iron, max., 0.06%. Castings from this bronze should have the following minimum physical properties: Ultimate strength, 30,000 lb. per sq. in.; yield point, 15,000 lb. per sq. in.; elongation in 2 in., 14%.

**Bronze Worm Gears.**—S.A.E. phosphor bronze, No. 65 and S.A.E. leaded gun metal, No. 63, may be used. The limits of composition and physical properties are: Copper, 88 to 90%; tin, 12 to 10%; phosphorus, 0.1 to 0.3%; lead, zinc and impurities, max., 0.5%. Ultimate strength, 35,000 lb. per sq. in.; yield point, 20,000 lb. per sq. in.; elongation in 2 in., 10%.

* Minimum. † Desired. ‡ A = Acid. § B = Basic.

The following are the limits of composition of the gun metal: Copper, 86 to 89%; tin, 11 to 9%; lead, 2.5 to 1%; phosphorus, max., 0.25%; zinc and impurities, max., 0.50%. The expected physical characteristics of good castings are: Ultimate strength, 30,000 lb. per sq. in.; yield point, 12,000 lb. per sq. in.; elongation in 2 in., 10%. These alloys, especially No. 65, are adapted to chilling for hardness and refinement of grain. No. 65 is preferred for worms of great hardness and fine accuracy. No. 63 is preferred for unhardened worms.

**Bronze Bushings for Gears.**—S.A.E. No. 64 is recommended, of the following analysis: Copper, 78.5 to 81.5%; tin, 9 to 11%; lead, 9 to 11%; phosphorus, 0.05 to 0.25%; zinc (max.), 0.75%; other impurities (max.), 0.25%. Minimum physical characteristics of castings are: Ultimate strength, 25,000 lb. per sq. in.; yield point, 12,000 lb. per sq. in.; elongation in 2 in., 8%.

**Brass Flanges for Composition Pinions.**—A.S.T.M. B 30–32T, and S.A.E. No. 40 are recommended. Composition is as follows: Copper, 83 to 86%; tin, 4.5 to 5.5%; lead, 4.5 to 5.5%; zinc, 4.5 to 5.5%; iron (max.), 0.35%; antimony (max.), 0.25%; aluminum, none. Minimum physical characteristics of the castings are: Ultimate strength, 27,000 lb. per sq. in.; yield point, 12,000 lb. per sq. in.; elongation in 2 in., 16%.

# CONTROL MECHANISMS

## GOVERNING, REGULATION, AND CONTROL

By W. Trinks

**References.**—Trinks, Governors and the Governing of Prime Movers, Van Nostrand, 1919; Stein, Regelung und Ausgleich in Dampfanlagen, Julius Springer, 1926; Wünsch, Regler für Druck und Menge, Oldenburg, 1930; Tolle, Die Regelung der Kraftmaschinen, Julius Springer, 1921; Behar, Fundamentals of Instrumentation, Instruments Publishing Company, 1932; Smith, Automatic Regulators, Their Theory and Application, *Trans.* A.S.M.E., PRO58-4, p. 291–303, 1936; Mitereff, Principles underlying Rational Solution of Automatic-Control Problems, *Trans.* A.S.M.E., FSP57-9, p. 159–163, 1935.

This section deals with fundamentals only; a complete treatise would fill a good-sized book.

### 1. PRINCIPLES

The words *governing*, *regulation*, and *control* have the same general meaning. Each means adjusting the supply (of power, heat, fluid, etc.) to the demand, or *vice versa*, thereby keeping constant one factor (speed, temperature, pressure, etc.) which is called the controlled quantity. Although the word *controlling* should be applicable to keeping any quantity constant, usage has made it impossible to adopt this term as a standard. We still say: Turbine speed is governed, water level in a boiler is regulated, temperature in a furnace is controlled.

All controlled equipment has self-regulating properties which limit the variation of that quantity which should remain constant, but the variations within the self-regulating range are, as a rule, too great to be allowed in practice. For example, an impulse turbine may reach nearly twice its normal speed if all of the load is removed. Any automatic-control installation consists of: 1. The controlled system; 2. The automatic-control apparatus proper. Through the controlled system there is a flow (of fluid or energy). Normally, *a*, inflow or supply and, *b*, outflow or demand are equal, and a factor or quantity, *c*, which is a function of the flowing medium, is kept practically constant (controlled, governed, regulated). Between inflow and outflow there is, in general, *d*, a storage capacity (tank, flywheel) which keeps down the suddenness of variations of controlled quantity *c*, if either inflow *a* or outflow *b* is changed. The automatic control apparatus consists of a measuring instrument, *e*, (also called primary element), which measures or at least detects (responds to) variations of the controlled factor *c*; an operating element, *f*, which adjusts in some cases the inflow and in others the outflow, if a disturbance occurs in either; and finally an operative connection, *g*, between the measuring (detecting) instrument *e* and the regulating or operating element *f*. In some cases, two of the elements are combined into one.

**GENERAL PRINCIPLE.**—A force is derived from the controlled quantity or variable, which latter may be speed, temperature, pressure, rate of flow, voltage, etc., and is balanced by an external, known force, *i.e.*, weight, spring, fluid pressure, etc., called the balancing force. Any change in the controlled quantity unbalances the measuring system; the unbalanced force, if sufficient to overcome friction, acts to re-balance the supply (inflow) and demand (outflow), and to bring the controlled quantity back to its normal value. The apparent defect that the supposedly constant quantity must change before the control apparatus can act, is almost overcome by making the necessary change exceedingly small, and by the advantage that governing is accomplished no matter whether the disturbance arises in the inflow (supply) or outflow (demand). Mathematically, the laws of governing, regulation, and control are locked up in differential equations; see the references cited.

### Definitions

**Direct-acting Governor, Self-operating Controller.**—If after a disturbance the unbalanced force moves, directly, the mechanism which adjusts the flow of power, fluid, heat, etc., the governor (on an engine or turbine) is called a direct-acting governor, and the controller (for pressure, temperature, etc.) is called a self-operating controller, or self-operating regulator.

**Relay Control.**—If the unbalanced force releases and controls a larger auxiliary force, which, in turn, adjusts the mechanism to restore equilibrium between inflow (supply) and outflow (demand), the controller is said to be of the *relay* type, or is called a *pilot controller.* The amplified force may be derived from a solenoid, an electric motor, from fluid pressure, or from motion of a prime mover.

**The Application.**—Control equipment now is manufactured in regular production, and is applied to many different controlled systems. Any one of these systems, consisting of inflow (supply), storage (capacity), and outflow (demand), is generally called the *application* by the manufacturers of automatic control apparatus.

**Modes of Control.**—After a disturbance, that is to say after a deviation of the controlled quantity from normal, the quantity may settle down to new equilibrium and remain quiescent until the next disturbance occurs. This is known as stable, steady or non-oscillatory control. For certain applications, as turbine speed governing, stability of regulation without oscillations is positively required. If the controlled variable oscillates continually about the normal value, the control is of the hunting type. For some industrial applications, as furnace temperature control, hunting within narrow limits is considered permissible. Control may be of the *on-and-off* or intermittent type, or it may be *floating,* in which case the regulating process (adaptation of supply to demand) is continuous. The on-and-off type necessarily hunts, but the floating type also may hunt.

**Regulation** has several meanings. In speed control, according to the A.S.M.E. Power Test Code, it is the ratio [difference between the maximum (ma) and minimum (mi) values of the controlled quantity] ÷ [arithmetical mean of these extreme values], or

$$(\text{ma} - \text{mi})/\{{}^1/_2\,(\text{ma} + \text{mi})\}$$

for stable or steady regulation and for the full scale of the measuring element. This ratio also is known as *static fluctuation, speed variation* or *speed droop.* In temperature control, as well as in close control of pressures near the atmosphere, division by the absolute temperature or pressure is inconvenient. In such cases the absolute change of the controlled quantity which is necessary to move the final or operating element from one extreme to the other sometimes is called *regulation*; more often it is known as the *throttling range*, or better, the *operating range*. These terms apply to slow changes of supply or demand. In some cases, *regulation* means that difference between the maximum and minimum values of the controlled quantity, either absolute, or expressed in terms of the average value, which occurs when the controller functions after a severe disturbance. If this difference be great, the *regulation is poor*. In this sense, regulation is synonymous with *dynamic fluctuation*, which latter always exceeds the static fluctuation (throttling range, regulating range). In Fig. 1, which is a chart drawn by a tachograph and which shows the change of speed of a steam engine after a sudden change to full load from no load, the static fluctuation (speed droop) is proportional to the vertical distance from 1 to 3, while the dynamic fluctuation is proportional to the vertical distance from 1 to 2.

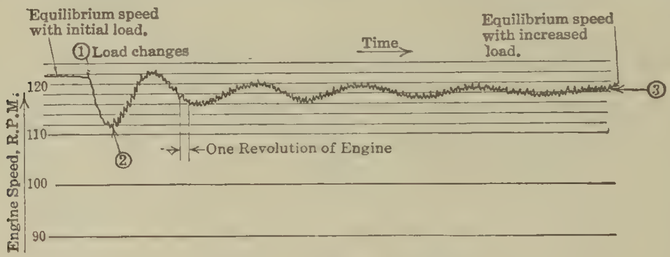

FIG. 1. Tachograph Record

**Sensitivity** and **Sensitiveness** often are used indiscriminately and, unfortunately, express several different concepts. Sensitiveness, as used in speed governing, is inversely proportional to the minimum change in speed which will cause the governor to move, and depends on the friction and lost motion in the governor or linkage. The term also, in accordance with older practice, is used to mean the travel of the governor for 1% change in speed. In the automatic control of quantities other than speed, the terms *ultimate sensitivity, dead range* (dead space, dead zone), or *sticking* (stiction, hysteresis) are used and are synonymous with sensitivity. The ultimate sensitivity of an instrument is inversely proportional to, and is measured by, the amount which the measured quantity may vary without moving the measuring element; this is indicated in Fig. 2, which illustrates the different meanings of the terms sensitivity or sensitiveness. A low ultimate sensitivity usually is caused by friction, but part of this effect is, in certain cases, ascribable to lost motion in the apparatus.

Sensitivity of a controller generally refers to the extent of movement of the pointer lever, or other position-changing element of the measuring instrument, required to cause the valve or other operating element to travel a definite but more or less arbitrary extent. Sensitivity in this sense is said to be high when the movement of the sensitive or primary element required to cause a given valve movement is small; that is, when the characteristic curves in Fig. 2 have steep slope. The *unit sensitivity* of the automatic controller sometimes refers to the value of the change in the measured quantity which is required to cause full valve travel. In that sense it is synonymous with the throttling range.

**Set Point** (Setting Point, Normality).—The value at which the controlled quantity is to be maintained often is indicated by the position of a pointer on the controlling instrument. This is called the set point, and represents the value at which the controller attempts to find equilibrium after each disturbance or load change. In simple devices, as reducing valves or direct-control governors, set pointers as a rule are not provided, but the adjusting screw or equivalent is the means by which the set point is changed.

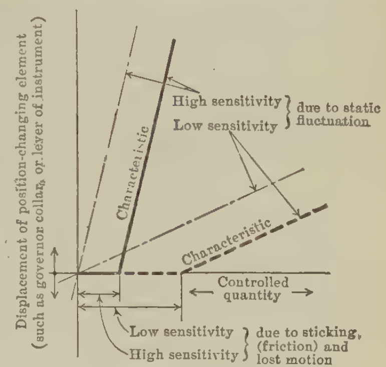

Fig. 2. Variations in Sensitivity

**Control Point** is the particular value of the controlled quantity at which the controller comes to equilibrium after a disturbance. In simple controllers, having a static fluctuation or droop, the control point will, at times, differ from the set point, depending on the load. In more complex types of instruments, the controller maintains the control point at the set point regardless of the load, except immediately after a disturbance.

**Time Lags**, *i.e.*, lapse of time between cause and effect, occur in both the controller and the controlled system (the application).

Lag in the controller is due to mechanical or thermal inertia, to capacity (storage), to lost motion, friction, damping, or to limitations of the supply of actuating energy. It exists in both the measuring and the operating element; a further lag exists in the connection between these elements, but its effects usually are negligible.

In the controlled system (the application), different time lags may exist separately or jointly. There may be a specific elapsed time, due to difference in location of the measuring and the operating elements, before the measured quantity is affected by the change in the supply or demand; this delay may be called the *distance lag*. There is also a delay due to the capacity of the controlled system; it is referred to as the *capacity lag*. The *impulse transfer lag* in the measuring instrument is the time required for transmitting a change in the immediate vicinity of the sensitive element to that element. The sum of these three lags is the *application lag*. In a few cases, the lag is increased still more by the difficulty that the measuring element (for example, a thermocouple) cannot be located at the place where the controlled quantity is to be kept constant, but ahead of it in the flow system. A *beyond-control* lag thereby is introduced, which likewise is part of the application lag.

Any lag or delay in the controlled system which reduces the suddenness of the change in the controlled quantity helps regulation, while any lag which results in lapse of time between change in controlled quantity and adjusting action of the controller makes accurate regulation more difficult.

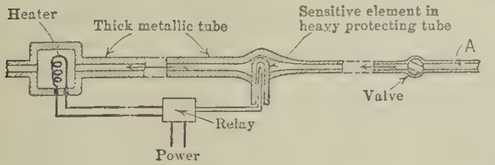

Fig. 3.

Fig. 3 illustrates the various lags in the controlled system. If the valve at the right is opened or closed, the temperature of the medium flowing past the heater is changed. 1. Time elapses while the fluid with changed temperature flows from the heater to the sensitive element; 2. Time elapses while the fluid exchanges heat with the surrounding metallic tube; 3. Time also elapses before the changed temperature of the fluid near the sensitive element can penetrate the protecting tube; 4. If the controlled quantity is to be kept constant at some distance to the right, *e.g.*, at point *A*, Fig. 3, of the measuring instrument, time elapses while the controlled quantity reaches its normal value at the location of the measuring instrument and at the desired location. In speed control, energy which has flowed beyond the throttle persists for a while in changing the speed of the engine or turbine. The second time lag mentioned is beneficial, the other three are harmful to regulation.

**Speed of Response** (promptness) as contrasted with sluggishness, is a measure of the rate at which the measuring instrument follows a sudden variation of the measured (and controlled) quantity. In addition to sticking, lost motion, inertia (mass action), damping, and impulse transfer lag make a primary element sluggish. Speed of response can be measured by the traversing time. The latter is the time during which either a self-operating controller, or the primary element of a relay control, travels from one end of the control range to the other, when actuated and accelerated only by the external balancing force. Example: The centrifugal weights of a non-rotating speed governor are pulled apart to the outer stop, and released. The time required to reach the inner stop is the traversing time. For the average spring-loaded speed governor, the traversing time ranges from 0.04 to 0.06 second; for weight-loaded governors, from 0.10 to 0.20 second. In pressure control, if the bell of the apparatus shown in Fig. 4 is raised to the top of its travel, is released, and falls (due to its own weight) to the bottom of the regulating travel, the time of falling is the traversing time. In many cases of automatic control, changes are so slow that speed of response is no object. This also applies to speed control.

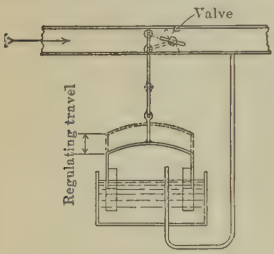

FIG. 4.

**Speed of Controlling** is measured by the time required for the equilibrium-restoring element (control unit) to move from one extreme position to the other, through the throttling range, under the action of the wide-open primary element. In self-operating controls, it is inversely proportional to the traversing time. In relay controls it is inversely proportional to the traversing time of the relay alone.

**Strength** is that force, exerted at the control point, which the balancing force of the instrument exerts when the external balancing force alone, unhindered by friction, acts. Knowledge of the strength is important for self-operating control equipment, such as direct-control governors and reducing valves, because the ratio (frictional resisting force of control mechanism) ÷ (strength) determines the relative or percentage variation of the regulated quantity which must be incurred for overcoming the frictional resistance of the control mechanism. In relay control, strength is generally of less importance.

**Regulating Force** is that fractional part of the strength which is available for overcoming resistance in the control mechanism or in the relay mechanism. In centrifugal speed governors, the regulating force for $P$ percent change of speed equals $2P$ percent of the strength, if friction in the governor is eliminated. In pressure governors, for $P$ percent change of regulated quantity, the regulating force is $P$ percent of the strength; in temperature control with radiation pyrometers, it is $4P$ percent. Since only small changes of the regulated quantity are allowed in practice, the regulating force never can be more than a small fraction of the strength.

**Work Capacity** of the primary element is of importance for self-operating controls only. It is the product of (average strength × distance through which it moves for the useful range of the control instrument). Only a very small fraction of the work capacity is available for doing work in overcoming resistance offered by the equilibrium-restoring mechanism. The work capacity of a relay is the product of (average static force × maximum travel of relay).

**Temporary Stability.**—Control with an absolutely constant value of the regulated quantity (except with a short deviation following a disturbance) is possible, if a change of controlled quantity, as a function of the load, is permitted during a disturbance and is, later on, automatically wiped out either by leaky gag-pots floating between springs or by a *double response*. (See below.)

**Asymptotic Regulation** in controllers with temporary stability is that type in which the rate of change of controlled quantity decreases as the control point is approached.

**Isoposic*** **Regulation** is that type in which the control mechanism comes to rest with the same value of the quantity to be controlled for all positions of the control mechanism (if the load changes very slowly); or in which the long-time static fluctuation, or droop, is zero. The term describes performance only, which may be obtained by different mechanisms. Regulators for pressure, rate of flow, or temperature, having this characteristic, sometimes are called *non-corresponding*, while speed governors of this type are called *isochronous governors*. The strictly isochronous governor, unaided by tangential inertia or by temporary stability, cannot be used, because by its dynamic interaction with the prime mover, it produces excessive and incessant fluctuations of speed.

---

* From Greek "Iso," the same, "Posos," quantity.

## 2. RELATION BETWEEN CONTROL INSTRUMENT AND APPLICATION

In the use of control apparatus, the latter may be built especially to be an integral part of the application, as for instance a shaft governor on a steam engine, of which it is a part. In the great majority of cases, a commercial control apparatus is purchased separately and applied to the controlled system (the application). The commercial controller, in this very common case, must have enough adaptability and adjustments to fit many different systems. The purchased control apparatus has no influence on factors affecting controller performance which are inherent in the application, as: 1. Lag due to storage of fluid, or enegry, beyond the control of the regulating element; for example, steam stored in multi-stage engine when load changes. 2. Impulse transfer lag to the measuring instrument, or primary element; for example, the thickness and material of the protecting tube of a thermocouple frequently are prescribed by the owner of the controlled system. 3. Suddenness and amount of disturbance; for example, power demand suddenly removed by kicking open of a circuit breaker.

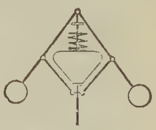

Fig. 5. Simple Speed Governor

If great time-lags (p. 15–05) are coupled with very sudden or very great disturbances, the very best control apparatus cannot produce close regulation. Lack of understanding of this situation has caused much quarreling between purchaser and seller of automatic control equipment, and keeps prices of control equipment high, because the cost of difficult installations, which require many trips of service men in the attempt to make them work satisfactorily, must in the long run be distributed over all, and even the simplest, control equipment and installations. Sufficiently early contemplation of control equipment in the design of systems would overcome many of these troubles.

## 3. TYPES OF CONTROL EQUIPMENT

The multiplicity of types is so great that only the most important ones can be mentioned here.

**SELF-OPERATING CONTROL APPARATUS.**—This type is exemplified by engine governors, by float control of water level in tanks, water closets, or sometimes in steam boilers, and by reducing valves. Of necessity, regulation is continuous or floating. For stability of regulation, without hunting, and also for parallel operation, a static fluctuation or regulation of low sensitivity is required, at least during a disturbance. Its use is limited to those cases in which a considerable force can be derived from the controlled quantity, and in which the frictional resistance of the equilibrium-restoring operating mechanism either is small or can be made small by vibration. Small mass of parts in measuring instruments is desirable, to prevent hunting. Self-operating controllers are subject to upsetting influences from unbalanced valves or valve gears; in particular, butterfly valves. Examples of self-operating regulators are shown in Figs. 5 to 10. Fig. 5 shows diagrammatically a simple form of speed governor. Fig. 6 shows a highly-developed spring-loaded speed governor of the Jahns type (Massey Machine Co.); its properties are given in Table 1. Fig. 7 shows a simple form of spring-

**RELAY TYPES.**—Most commercial automatic control equipment is of the relay type. The advantages are: Measuring instrument is small, and it is not subject to upsetting forces due to variable resistance of equilibrium-restoring mechanism. It has the disadvantage of complication, and of cost in small controlled systems. For example, the control for a small, simple heat-treating furnace sometimes costs more than the furnace itself. Relay controls are of the following types:

**1. Proportional (corresponding) Control** with coupling-back (stabilizer, rigid return, precision action, vernier valve action, valve positioner).—For examples, see Figs. 12 to 14. The coupling-back causes the movement of the relay to be proportional to the movement of the sensitive element. The action of this type of control is identical with that of the self-operating type, but with amplification of the regulating force of the primary element. In consequence it has a static fluctuation, or droop. In practice, two or three amplifications in series occasionally are employed. A compact double relay in which a floating element is at once the primary relay piston and the secondary relay valve is illustrated in Fig. 11. Coupling-back is accomplished by a rigid return of the pilot valve as in the speed governor of Fig. 12; or by a stabilizing spring, as in the speed governor of Fig. 13, or in the pressure control of Fig. 14; or by still other means. Amplification may include conversion from one type of energy into another type, for instance conversion from electrical energy into fluid-pressure energy.

Fig. 14. Relay Pressure Control with Stabilizing Spring

**2. Continuous Control** without coupling-back. In this type, the relay equipment, once set in motion, is stopped only by a reversal of motion of the primary sensitive element. This is a simple type of control which is used where the load changes are relatively gradual and where the application lag is small. In general, it allows the control point to shift about the set point, and thus causes hunting unless the controlled system has inherent stability, as for instance in pressure control. It seldom is used in speed governing, but is common in pressure control. See Fig. 15.

**3. Isoposic Control with Relay.**—Proportional (corresponding) control with slowly yielding coupling-back, or slowly yielding return. This type is identical in action with No. 1 during a disturbance, which means that it has a static fluctuation during a disturbance. However, the interposition of a slowly-yielding return element, such as a spring-pressed oil pot, removes the static fluctuation and returns the controlled quantity to its original value. The mechanism which returns the controlled variable to normal value has many names; it is referred to as a follow-up, a reset, a stabilizer, a double response, a compensator of the second order. Control of this type is extremely useful in cases where there is a large application lag, because it eliminates hunting, while permitting practically constant value of the controlled quantity regardless of the load, except immediately after a disturbance. A speed governor of this type is shown in Fig. 16, and two pressure con-

trols in Figs. 17 and 18; in the former, the slowly yielding return element is an oil gag-pot; in Fig. 18, it is a double bellows with a capillary resistance-tube. In the latter type, adjustment of damping action is obtained by variation of effective length of lever arm on which double bellows act.

**4. Anticipator Control.**—The name is misleading, but was originated to indicate that when the controlled quantity was returning to normal, the control action would anticipate the complete return to normal. This type of control is the same as No. 3, with the exception that, by any one of various means, a large correcting motion of the valve or operating element is caused to occur in the early stages of a controlling action after a disturbance, followed by a gradual decrease of the valve motion as the instrument approaches equilibrium. A variety of specific designs of instruments fall into this classification. This type of control is useful in cases with great time lag, for enforcing stability of regulation and preventing hunting. The same effect also can be obtained by intermittent control (see p. 15–12).

Fig. 18. Relay Pressure Control with Yielding Return. Capillary Resistance Tube

Another type of anticipatory control, which is useful for applications having considerable time lag, does actually anticipate the change of controlled quantity at the measuring instrument.

Example.—In control of temperature in residences, the thermostat located in a room may be acted upon not only by the heat of the room air but also by a very small electrical heating-coil partly surrounding the thermostat and energized when the motor- or solenoid-operated burner of the furnace is in operation. When the burner is idle, the thermostat may be cooled by evaporating water.

**5. Interrupted or Intermittent Control.**—Regulating action is interrupted after an adjustable regulating movement and is resumed at intervals, if the control point has not yet returned to normal position. The waiting time between, and the extent of each of the regulating movements, are made adjustable. This type of control was designed to imitate the actions of a cautious human operator.

**6. Two-point and Three-point Control.**—This type of control also is called two-position and three-position control. Control systems using electric contacts are frequently of the on-or-off type, or of the high-or-low type. They are continually hunting, unless the motion of the motor is periodically interrupted, as above indicated, or two motors with differential action are used. The motion of electric motors cannot be damped without complication.

In the three-point control, when the controlled quantity is at the correct value or within a narrow range on either side of it, the control is at rest. Unless the band on either side of the correct value is made rather broad, this control likewise is of the hunting type. The amplitude and frequency of the hunting depend on the character of the controller as well as on that of the applications. Numerous innovations have been introduced in controllers in order to minimize it.

## 4. REQUIREMENTS FOR GOOD CONTROL (REGULATION)

**DIRECT-ACTING, SELF-OPERATING CONTROL.**—The combined measuring instrument and motor must be nearly free from friction, or must be freed from friction by vibration. In most cases, damping by liquid friction is needed. Mass of the instrument, and the distance through which the mass travels, should be small. The strength of the regulating instrument must be very great compared to the frictional resistance of the equilibrium-restoring mechanism. The latter must not exert a greatly variable force on the measuring instrument. Damping, as well as static fluctuation, should be adjustable. All time lags should be reduced to a minimum. Regulation (static fluctuation, stability) is required, at least temporarily, to prevent hunting.

**RELAY GOVERNING.**—The measuring instrument must be practically free from friction and have small inertia. The sensitivity of the control, that is, the motion of the regulating mechanism for unit change of controlled quantity, must be adjustable. The speed of adjusting of the regulating mechanism (controller time) must be adjustable in certain types. It should be quick at the start, slowing down as the new position is approached. A reset, follow-up, compensator, or double response, all these terms having the same general meaning, is desirable in most cases. In speed control, the relay must move quickly.

The relay mechanism must not exert so much reaction against the measuring instrument as to unbalance the latter. If danger of reaction exists, for instance, from a large pilot valve, a double or floating relay is used. See Fig. 11.

## 5. FORCES USED IN GOVERNING, REGULATION, AND CONTROL

**SPEED CONTROL.**—Centrifugal force (radial inertia) of weights pivotally mounted and revolving around a shaft is most commonly used. Oil pressure generated by a centrifugal pump, and air pressure generated by a fan or turbo-blower, also have been used. Tangential inertia (tangential acceleration) was tried on account of its anticipatory character, but is a failure unless coupled with centrifugal force, when it is useful for shaft governors.

**PRESSURE CONTROL.**—Pressure exerted against a floating bell, or a diaphragm membrane, or liquid in a U-tube manometer, furnishes the force for low pressures, while the Bourdon tube is useful for high pressures. A piston in a cylinder has too much friction, unless rotated, in which case it can be, and often is, used for high pressures. Change in rate of flow, either of the supply or demand, also has been used for pressure control. However it is unsatisfactory unless used in connection with control by force derived from controlled pressure.

**RATE-OF-FLOW CONTROL.**—This is reduced to pressure control by making use of the pressure drop through an orifice, nozzle, or Venturi tube; the only difference being that pressure acts on both sides of a diaphragm, instead of on only one side; or, instead, two floating bells are balanced against each other. A Pitot tube can be used in place of the orifice. In addition to constant pressure drop, if constant rate of flow is to be maintained, the viscosity of liquids and the density of gases must be kept constant. The former may call for auxiliary temperature control. The latter may require both temperature control and pressure control.

**CONTROL OF LEVEL OF LIQUID.**—The buoyancy of a float is the most commonly used force. In control of water level in boilers, difference of temperature between steam and water has been utilized. See Fig. 9.

**CONTROL OF TEMPERATURE.**—For temperatures below red heat, temperature changes often are converted into pressure changes by means of gases or vapors enclosed in bellows. See Fig. 10. Gases in bulbs connected to Bourdon tubes also are used. Difference in expansion of solids, exemplified by curved bimetallic strips, etc., also produces a force. Electric current, started by an electric resistance thermometer, flowing through a solenoid produces a force which is used for regulating purposes. For temperatures above red heat, thermocouples and radiation pyrometers are used. A thermoelectric current moves the pointer (control pointer) of a galvanometer, or potentiometer. The pointer is depressed at regular intervals and closes circuits on "high" or "low" contacts, whereby relays are set in action to start motors which move the equilibrium-restoring mechanism. Radiation pyrometers are used in the same way. They also are used to send current through a solenoid which deflects a regulating jet of oil. Instead of a pointer, a light beam may be used to actuate a photoelectric cell.

**CONTROL OF MIXTURE RATIO OF FLOWING FLUIDS.**—This is reduced to pressure control by letting each fluid produce a differential pressure, the same as in control of quantity of fluid flowing, and balancing the two pressure differences against each other. The densities of the two fluids must be controlled in order to avoid variations in the mixture ratio.

**CONTROL OF HUMIDITY.**—The hygroscopic properties of cross-grained wood or of human hair commonly are used in the primary element. In more elaborate instruments, wet and dry bulb temperature difference is used to effect the regulation by means of either vapor-filled thermometers or electric resistance thermometers or thermocouples.

**COMBUSTION CONTROL** generally consists of simultaneous control of furnace pressure and of fuel-to-air ratio. For pressure control see above. For clean gaseous fuels and for liquid fuels, control of fuel-air ratio is reduced to that of controlling the mixture ratio of flowing fluids, for which see above. If oil fuel is used, its temperature must be kept constant, to avoid changes in viscosity, because such changes upset the reading of the pressure differential. No force has been derived satisfactorily from the flow of raw producer gas, on account of clogging of instruments, in particular the measuring orifice, by tar.

Combustion control in the power plant involves control of powdered coal or of stoker feed, neither of which can be measured accurately. The consequence is that indirect methods are used. Since combustion control in the power plant is highly special, it cannot be described here.

**POTENTIAL (VOLTAGE) CONTROL OF ELECTRICAL GENERATORS.**—A force proportional to the voltage is derived from a current passing through a constant-resistance coil. In alternating-current generators, rectifiers sometimes are used to convert alternating current to direct current. The force, acting by rectilinear motion or by producing torque, changes the field resistance in direct-current generators, and either generator-field or exciter-field resistance in alternating-current generators. Stability easily is obtainable through magnetic damping. The use of electron tubes also gives powerful methods of control.

**PROGRAM REGULATION.**—Instead of the controlled quantity being held approximately constant, it may be made to vary automatically with time, according to a predetermined program. For example, the temperature of an annealing furnace may be made to increase gradually over a long period of time and then to decrease slowly, allowing the charge to cool at a rate in accordance with the metallurgical requirements. The general principle utilized in program regulation is the controlled shifting of the set point or control point by a cam actuated by a clock, or by some other form of constant-speed device, usually electric.

Not only one quantity but all the important quantities of a process may be made to vary automatically according to a program laid out in advance, by mounting several cams, controlling pressure, temperature, rate of flow, etc., respectively, on a shaft turned at constant slow speed under control of the clock. The program itself may be varied by changing the cams and the speed of the shaft.

**CYCLE CONTROLLERS** are similar to program controllers with the exception that they do not hold any quantity constant but simply open and close valves in a pre-determined sequence. An example is automatic reversal of blast-furnace stoves.

## 6. CONTROL TROUBLES AND THEIR REMEDIES

Regulation troubles may be due to causes having to do with the metering device, with the motor device or operating element, or with the connection between the two. Furthermore, these causes originally may have existed in, or even may be inherent in, the design of the regulator, or they may arise only after the device has been in operation for some time. In the latter case they usually are caused by wear, increased friction, clogging, or leakage.

**HUNTING.**—Troubles include hunting. In speed governing, hunting also is called racing, pumping, or surging. If the control acted correctly at first, and hunting develops only after the installation has been in operation for some time, the primary element first should be checked to see that it responds. If it operates correctly one or more of the following items may be the cause: Insufficient oil in the gag-pot; oil in gag-pot too light; adjustment of oil pot not tight enough; friction in governor or in instrument mechanism or in operating element or stuffing box. To ascertain whether or not friction is responsible for the hunting, move the governor collar or the controller by hand alternately in either direction with equal force. If hunting disappears while the controller is being oscillated, friction is responsible. To ascertain whether or not friction in the relay mechanism is too great for the relay force, try to move the mechanism by hand or by a lever in the direction of least resistance, and keep it up for some time, helping the relay along. If hunting becomes noticeably less, the friction is in the relay mechanism. Hunting also may be caused by leaky pilot valves and worn-out oil pumps; by too low a pressure of air supply or oil supply to the control; by dirt in the air- or oil-pilot valve; in electrically-operated devices, by too low a supply voltage, or dirty contacts. Lost motion in the relay mechanism has a similar effect. A weak spring or weight, keeping the joints in contact always in one and the same direction, can be used to eliminate lost motion. In devices using diaphragms, trouble may be caused by the latter wearing out or cracking.

In any control, trouble may be caused by overload, *i.e.*, demand for the controlled quantity beyond the range in which the control was designed to operate, or by any considerable change in the application or method of use.

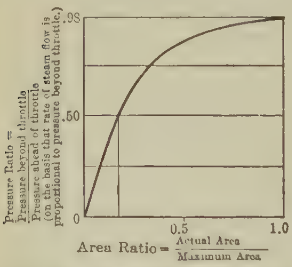

FIG. 19. Characteristic Curve of Throttling Valve

In speed governing, hunting or racing also may be caused in releasing-gear (Corliss) engines by dulling or rounding of the knife edges of the catch blocks, or by improper adjustment of the vacuum pots. Slipping governor belts, too, often are responsible. Speed adjustment of variable-strength governors often produces racing. If the racing starts with the first operation, it may have the same causes, but there are additional causes which, once removed, do not return. If racing occurs near one certain position of the governor or valve gear, the stability of the governor in that position is too small either from: 1. Wrong design of governor; 2. Because the power control mechanism does not vary the supply of energy uniformly with the travel of the governor; 3. Because forces from the power control mechanism react upon the governor. Case 1 can be determined by running the governor on a test block. All three cases usually yield to the application of springs which act over a small part of the governor travel only, and increase stability over that part. See Fig. 5, in which the spring enters into action near the no-load position. Case 2 frequently is encountered, because, near the closed position of a throttle valve, a small increase in area changes the flow through the valve much more than it does if the valve is almost wide open. See Fig. 19. This feature, which has been a prolific trouble maker in governing and regulation, can be counteracted by providing a linkage or cam arrangement between the governor, or other primary element, and the throttle, or else by a valve design in which a given increment of valve lift uncovers fewer square inches near the closed position than it does near the open position of the valve.

In addition to the cited causes, hunting at any load may be caused by too small a static fluctuation of the primary element. This can be remedied by using a greater part of the instrument travel, or by adding a stability-producing spring to the apparatus.

# BRAKES *

**FRICTION BRAKES** are used: 1. To slow or stop a machine by converting its energy of motion into heat; 2. To control the speed of a descending load. Brakes may be classified as block brakes, band brakes, axial brakes, and load brakes.

The following points must be considered in the design of brakes: 1. Each part must have sufficient mechanical strength safely to withstand the maximum load that will come upon it during operation. 2. The pressure per unit area of surface must not be taken so high that excessive wear will result. 3. The coefficient of friction should be carefully considered; its value depends on the materials in contact, on the presence or absence of lubricating matter, and on the rate of slippage. With metal on metal, with increased velocity of slip, the coefficient of friction decreases from its value as the coefficient of friction of rest; the reverse, however, is true of leather. 4. The heat generated by the rubbing surfaces must be so dissipated as not to injure the brake.

## 1. BLOCK BRAKES

**RESISTANCE OF BLOCK BRAKES.**—The simplest form of brake is the block brake, commonly used for railway car wheels, and in some forms for hoisting engines. In the car wheel brake the resistance is not only that of sliding friction, but the resistance of cutting or grinding away the surface of the metals in contact. If $P$ = total pressure acting normal to the sliding surface, lb., $\mu$ = coefficient of friction, $V$ = velocity of sliding, ft. per min., then the energy absorbed by the brake is $PV\mu$ ft.-lb. per min. Values of $\mu$ may be taken from the tables, pp. 8–23 to 8–28. It should be noted that the value of $\mu$ is different for lubricated and unlubricated surfaces. If pressure $P$ is great enough to

**Table 1.—Block Brake Formulas.**

$P$ = force at end of brake lever, lb.; $F$ = tangential force at rim of brake wheel, lb.; $R$ = reaction between brake wheel and block, lb.; $\mu$ = coefficient of friction; $P(a + b) = R\,b$.

squeeze out the lubricant, the value of $\mu$ increases, and the surfaces will cut and wear with an increase of temperature.

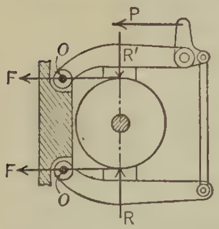

FIG. 1. Double Block Brake

**Block Brake Formulas.**—Various arrangements of block brakes are possible. Formulas for different arrangements of single block brakes are given in Table 1. If the faces of the sliding surfaces are grooved, the values given by formulas [1] to [6] should be corrected as shown in the table. In the single block brake, the reaction $R$ of the brake shoe is opposed by an equal and opposite reaction $R'$ at the bearing. The braking effect resulting from the friction of the journal can be neglected in designing the brake, but should be considered in the design of the bearing. The single-block brake tends to bend the shaft. In the double-block brake, Fig. 1, reactions $R$ of the two blocks are equal and opposite, and tendency to bend the shaft is eliminated. The braking force is equal to twice the value given by equation [2]. If the line of action of $F$ passes either inside or outside of fulcrums $O$, the braking load is not the same at the two blocks, and a tendency to bend the shaft exists. The total braking load is the sum of the loads given by equations [3] or [5] as the case may be.

## 2. BAND BRAKES

A band brake consists of a band or strap, usually of steel, sometimes of leather wrapped around the major portion of the circumference of the brake wheel, so connected to levers that it may be tightened on the wheel. In another form, used in some automobile brakes, the band is expanded against the internal circumference of a hollow brake drum. The

**Table 2.—Formulas for Band Brakes**

$P$ = force at end of brake lever, lb.; $T_1$ = tension in tight side of band, lb.; $T_2$ = tension in slack side of band, lb.; $F = T_1 - T_2$ = tangential force at rim of brake wheel, lb.; $\mu$ = coefficient of friction between band and wheel; $e$ = base of Naperian system of logarithms = 2.17828; $\alpha$ = angle of contact of band with wheel, radians (1 radian = 57.296 deg.).

[14]<br>For counter-clockwise rotation, $P = \dfrac{F}{a}\left\{\dfrac{b_1 e^{\mu\alpha} + b_2}{e^{\mu\alpha}-1}\right\}$ . . . . [15]<br>If $b_1 = b_2 = b$, for both cases, $P = \dfrac{Fb}{a}\left\{\dfrac{e^{\mu\alpha}+1}{e^{\mu\alpha}-1}\right\}$. . . . . [16] |

brake wheel may be of cast iron or steel, or it may be faced with leather or wood. The band itself may be lined with a special brake lining, as in automotive practice, possessing a high coefficient of friction and high temperature resistance. See Kent's Mechanical Engineers' Handbook—Power, p. 14–73, forming Vol. 2 of this series.

**RESISTANCE OF BAND BRAKES.**—The theory of band brakes is the same as that of the friction of belts. See p. 24–14. The fundamental equations are:

$$F = T_1 - T_2 \qquad [17]$$

and

$$T_1/T_2 = e^{\mu\alpha} = 10^{0.00758\mu\theta} \qquad [18]$$

where $F$ = total friction of the band on the wheel, $T_1$, $T_2$ = respectively, tensions in tight and slack sides of the band; $e$ = base of Naperian system of logarithms = 2.71828; $\mu$ = coefficient of friction; $\alpha$ = arc of contact of band with the brake wheel, radians; $\theta$ = arc of contact, degrees. Values of $e^{\mu\alpha}$ are given in Table 3. Table 2 shows various arrangements of band brakes and the formulas applicable thereto.

**Table 3.—Values of $e^{\mu\alpha}$**

## 3. AXIAL BRAKES

Axial brakes are those in which resistance is applied by the axial movement of the braking members. Two general forms are in use, cone brakes and disc brakes.

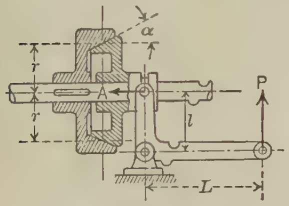

Fig. 2. Cone Brake

**CONE BRAKES.**—Fig. 2 illustrates one form of cone brake. Force $P$ applied to the brake lever $L$ causes axial movement of the brake cone into its mating shoe, thus creating resistance to the rotation of the member to which the shoe is attached. Let $M$ = twisting moment on brake shaft, in.-lb.; $r$ = mean radius of brake wheel, in.; $P$ = pull on lever, lb.; $F = M/r$ = force at the circumference of the brake wheel, lb.; $\alpha$ = half angle of the cones; $\mu$ = coefficient of friction between brake wheel and shoe; $A$ = axial pressure, lb., along the cone shaft forcing the cones together; $N$ = normal pressure on the cone, in order that the braking action shall overcome the turning moment; $L$ = length of lever, in.; $l$ = distance from fulcrum of brake lever to axis of cone. Then

$$F \gtrless 2\mu N \qquad [19]; \qquad A = PL/l \qquad [20]$$

$$N = \frac{A}{2(\sin\alpha + \mu\cos\alpha)} \qquad [21], \quad \text{or} \quad \frac{A}{2\sin\alpha} \qquad [22]$$

$$F \gtrless \frac{A}{\sin\alpha + \mu\cos\alpha} \qquad [23], \quad \text{or} \quad \frac{\mu A}{\sin\alpha} \qquad [24]$$

$$P \lessgtr \frac{Fl\sin\alpha + \mu\cos\alpha}{\mu L} \qquad [25], \quad \text{or} \quad \frac{Fl\sin\alpha}{\mu L} \qquad [26]$$

Angle $\alpha$ usually ranges from 10 to 18 deg. For cast iron on cast iron, $\mu$ can be taken as 0.12; for one surface of wood and the other of cast iron, $\mu$ = 0.25 may be used.

From an experimental investigation of a cone brake by Prof. H. Bonte (*Zeit. V. D. I.*, Dec. 15, 1915), Prof. Leutwiler (Machine Design, p. 419) derives the following conclusions concerning formulas [23] and [24]: 1. When $\alpha$ is 15 deg., the error introduced by using [23] is large, while the agreement between the experimental results and those obtained by using [24] is very close. 2. When $\alpha$ is 30 deg., the experimental results lie between those obtained by [23] and [24]. When plotted, the curve representing the results obtained by [24] lies above, but much closer to the experimental curve than that obtained by [23]. 4. For the angles 45 deg. and 60 deg., the experimental points lie above those obtained by [24], which in turn lie above the points obtained by [23]. 5. Apparently, the coefficient of friction is not constant, as generally assumed, but varies slightly with the pressure. As a result of this experimental investigation, Prof. Bonte recommends that [23], which apparently is incorrect, should not be used in the design of cone brakes or clutches.

**DISC BRAKES** are of the same general construction as cone brakes, excepting that the friction faces are discs instead of cones. Most brakes are of the multiple-disc type, *i.e.* having more than two friction faces in contact. With the same arrangement for applying axial pressure as in Fig. 10, let $n$ = number of friction surfaces in contact; $r$ = mean radius of friction discs; other notation as before. Then

$$A = F/n\mu r = Pl/L \qquad [27]$$

$$P = FL/n\mu lr \qquad [28]$$

$$F = Pn\mu lr/L \qquad [29]$$

See Load Brakes below for formulas dealing with the application of axial pressure by means of a screw instead of a lever.

## 4. LOAD BRAKES

Load brakes to control the speed of descent of load on cranes and hoists may be manually or automatically operated. They are made in several forms.

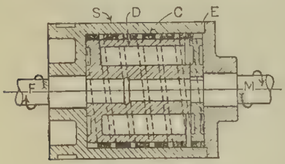

Fig. 3. Coil Brake

**COIL BRAKES.**—Fig. 3 shows a coil brake. Drum $D$ is keyed to the driven or follower shaft $F$ but is free to turn on the motor shaft $M$. Coil $C$ is made of flat rod wound into a helix, ground internally and externally. The external diameter is made slightly larger than the internal diameter of sleeve $S$ so that the coil must be slightly compressed when the brake is assembled. One end of the coil is fastened to flange $E$, which is keyed to shaft $M$; the other end is secured to drum $D$. In hoisting, motor shaft $M$ turns in the direction of the arrow at the right; this action expands the coil against sleeve $S$ and causes drum $D$ and shaft $F$ to revolve with the casing. If the motor stops, holding the load suspended, shaft $F$ and drum $D$ under the action of the load tend to turn in the direction of the arrow $F$; this expands the coil against the sleeve $S$, which is prevented from turning by a ratchet, not shown, on the end. To lower the load, motor $M$ reverses its direction, thus releasing coil after coil from contact with the casing; when sufficient coils have been thus released, shaft $F$ turns under the action of the load, in the direction of the arrow, which has the effect of again expanding the coil sufficiently to hold the load.

The coil brake is, in effect, an internal band brake, and the formulas used in the computation of band brakes may be applied. See p. 15–16. In applying these formulas $T_1/T_2 = K$. The value of $K$ may be obtained by $\log_e K = \mu\, l/r$, where $l$ = length of circular arc of coil in contact with the drum, and $r$ = radius of drum.

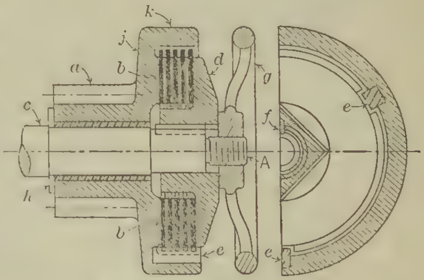

Fig. 4. Weston Brake

**DISC LOAD BRAKE.**—Fig. 4 shows a multiple-disc brake of the Weston type. This brake consists of a pinion $a$, bushed at $h$, and with a flange at $j$ which is extended to form the casing $k$; this casing encloses a series of friction discs which are made to rotate with it by means of the feathered keys $e$. Alternating with these discs are others fitted to the square hub of the flange $d$. The pinion $a$ is free on the shaft but the flange $d$ is keyed to the shaft at $f$. The hand-wheel $g$ enables the operator to control the speed of the load by increasing or decreasing the pressure between the discs. The shaft is held from running backward by a ratchet and pawl not shown.

Formulas [27] to [29] would be modified by use of the hand-wheel and screw as follows: Let $A$ = axial thrust on friction discs; $F$ = frictional tangential force on discs; $M_1$ = frictional moment between flange $d$ and hub of hand-wheel $g$; $n$ = number of frictional faces in sliding contact; $P$ = tangential force at circumference of hand-wheel; $R$ = radius of hand-wheel; $r$ = mean radius of friction discs; $r_1$ = mean radius of screw; $\mu$ = coefficient of friction between discs; $\theta$ = helix angle of screw; $\phi$ = friction angle of screw; all dimensions are taken in inches and all forces in pounds. Then

$$A = \{P R/r_1 (\tan \theta + \phi)\} - M_1 = F/n\mu r \quad . \quad . \quad . \quad . \quad [30]$$

$$F = n \mu r [\{P R/r_1 \tan (\theta + \phi)\} - M_1] \quad . \quad . \quad . \quad . \quad . \quad . \quad [31]$$

$$P \overset{=}{>} \{F r_1 \tan (\theta + \phi)/n \mu r\} + M_1 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [32]$$

Fig. 5 shows a form of disc load brake for traveling cranes. The pinion $F$ drives the hoisting drum. In hoisting, gear $A$, driven by the motor, is rotated on the screw in a direction that causes it to move axially on the shaft and clamp the friction faces $E$ of the ratchet wheel $B$ between the gear $A$ and the flange $C$ which are fast on the shaft. Ratchet wheel $B$ is prevented from rotating backward under the pull of the load by the pawl $D$. The load thus is sustained so long as pressure is maintained between $A$ and $C$. When the load is lowered, $C$ is held stationary by pawl $D$. The direction of rotation of gear $A$ is reversed, tending to unscrew it and remove the frictional resistance between it and flange $C$. However, the load will rotate the shaft, thus tending to screw the shaft into gear $A$ and so restore the friction. These two tendencies balance each other, and the load descends under control and at a speed determined by the speed of the motor. The force required to raise and lower loads is given by equations [33] and [34], in which $P$ = tangential force acting at mean radius of load, $r_1$ = mean radius of thread; $r_2$ = mean radius of friction faces $E$; $s$ = pitch of thread; $\mu$ = coefficient of friction between friction faces of $A$, $B$, and $C$; $\mu_1$ = coefficient of friction between screw and nut; $W$ = load. All dimensions are in inches, and all loads and forces in pounds.

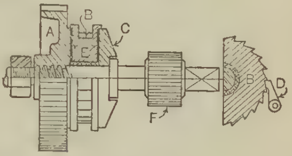

Fig. 5. Load Brake for Traveling Crane

To raise load $$P r_1 = W r_1 \left\{\frac{s + 2 \mu_1 \pi r_1}{2 \pi r_1 - \mu_1 s}\right\} + \mu W r_2 \quad . \quad . \quad . \quad . \quad . \quad . \quad [33]$$

To lower load $$P r_1 = W r_1 \left\{\frac{2 \mu_1 \pi r_1 - s}{2 \pi r_1 + \mu_1 s}\right\} + \mu W r_2 \quad . \quad . \quad . \quad . \quad . \quad . \quad [34]$$

In determining the value of $P r_1$ for raising the load, the acceleration of the load must be considered and added to the actual load being lifted. The acceleration load is equal to $W a/g$, where $a$ = acceleration, ft. per sec. per sec., and $g$ = acceleration due to gravity = 32.2.

MAGNETIC AND ELECTRIC BRAKES.—For braking the load on electric cranes a band brake sometimes is used which is held off the drum by the action of a magnet or solenoid, and is put on by the action of a spring or weight. The solenoid usually consists of a coil of wire connected in series with the motor, and a plunger working inside of the coil. It should be so proportioned that its action is not delayed by residual magnetism when the current is cut off. Too rapid action is prevented by making the end of the solenoid an air dash-pot.

For electrically-driven machinery an electric motor makes a most efficient brake by reversing the direction of the electric current, causing the motor to become a generator supplying current to a rheostat in which it is converted into heat and dissipated. In some cases the electric current generated, instead of being absorbed in a rheostat, is fed into the main electric circuit. In this case the energy of the rotating mass, instead of being wasted in friction or in electrical heating, is converted into electric energy and thus conserved for further use.

## 5. COEFFICIENT OF FRICTION AND HEAT LOSSES

COEFFICIENT OF FRICTION.—The coefficient of friction is highest for static conditions and decreases with increase of velocity. According to Galton (Hess, Mach. Design), the coefficient of friction of cast-iron brake shoes on steel tires varies with the velocity as follows:

| | | | | | | |
|---|---|---|---|---|---|---|
| Velocity, ft. per min. | Beginning | 440 | 880 | 2200 | 4000 | 5250 |
| Coefficient of friction | 0.330 | 0.273 | 0.242 | 0.166 | 0.127 | 0.074 |

Wichert has determined the effect of velocity upon the coefficient of friction for cast-iron brake shoes upon steel-tired car wheels to be approximated by the following formula,

$$\mu = B\{(1 + 0.002\,V) \div (1 + 0.0011\,V)\} \qquad [35]$$

where $B$ = coefficient of friction of rest under the given condition of the surfaces relative to each other; $V$ = velocity, ft. per min.

Brake tests made by the Penna. R.R. indicate that coefficient of friction decreases with hardness of the cast-iron brake shoe, and that the maximum possible coefficient of friction is obtained with a Brinnell hardness of about 190.

The coefficients of friction for materials used for brakes, for velocities ranging from 180 to 3900 ft. per min., and pressures from 7 to 140 lb. per sq. in. are given in Table 4.

**Table 4.—Coefficients of Friction for Brake Materials.**

(From Various Sources)

| Brake Material | Value of $\mu$ on | | Brake Material | Value of $\mu$ on | |
|---|---|---|---|---|---|
| | Cast Iron | Wrought Iron | | Cast Iron | Wrought Iron |
| Beech | 0.29–0.37 | 0.54 | Fiber | 0.10–0.20 | ........ |
| Bronze, lubricated | 0.06–0.10 | .... | Leather, dry | 0.3 | ........ |
| Cast iron, dry | 0.25–0.3 | .... | " , lubricated | 0.23 | ........ |
| " " lubricated | 0.08–0.12 | .... | Oak | 0.30–0.34 | 0.40–0.51 |
| Cork * | 0.35 | .... | Poplar | 0.35–0.40 | 0.49–0.65 |
| Elm | 0.36–0.37 | 0.49–0.60 | Willow | 0.46–0.47 | 0.60–0.63 |

* See also p. 8–23.

**HEATING OF BRAKES.**—The energy absorbed by a brake must be dissipated as heat. Consequently, the brake should be designed with ample radiating surface, ribs or fins being provided if necessary, to promote rapid dissipation of heat. Referring to Fig. 5, the energy absorbed by a disc brake is as follows: Let $E$ = energy absorbed by brake, ft.-lb. per min.; $r_o$, $r_i$ = respectively, inner and outer radii of friction discs, in.; $r$ = mean radius of screw, in.; $n$ = number of friction surfaces in contact; $N$ = revolutions per min.; $p$ = total pressure on friction discs, lb.; $S$ = area of radiating surface, sq. in.; $H$ = total heat to be dissipated, B.t.u. per min.; $T$ = torque, in.-lb., on pinion $F$; $\theta$ = helix angle of screw; $\phi$ = friction angle of screw. Then

$$E = \frac{2}{3}\left(\frac{r_o^3 - r_i^3}{r_o^2 - r_i^2}\right)\frac{\pi}{12}\,n\mu N p \qquad [36]$$

$$p = T/r \tan(\theta + \phi) \qquad [37]$$

$$H = E/(778 \times 2\,S) \qquad [38]$$

The heat dissipation is a function both of the temperature of the brake and of the time that it is at rest betweeen applications, during which heat is being radiated. Let $m$ = number of minutes the brake is at rest; $t_1$, $t_2$ = minimum and maximum temperatures of the brake drum, deg. F.; $c$ = mechanical equivalent of the specific heat of the brake-drum material = (specific heat/778); $k$ = radiation factor; $w$ = weight of brake drum rim, lb.; $S$ = area of radiating surface, sq. in. Then

$$\log(t_2 - t_1) = 0.434\,k\,S\,m/c\,w \qquad [39]$$

and

$$E = c\,w\,(t_2 - t_1) \qquad [40]$$

Values of $k$ range from 0.4 to 0.8 per min. per deg. F. temperature difference above the surrounding air. Values of $t_2$ may range from 200° F. with wood friction blocks, to 500° F. with asbestos friction surfaces.

# VIBRATION AND NOISE

By Arthur L. Kimball

## VIBRATION

**FREE AND FORCED VIBRATIONS. RESONANCE.**—It is important to differentiate between *free* and *forced* vibrations. Free vibration occurs when the driving force is removed, dying out more or less gradually. Forced vibration is maintained by a driving force. The former has a frequency of its own; the latter can have any frequency, depending on that of the driving force. If the frequency of the driving force is in step with the natural or free period of the vibration, the forced vibration will build up to a large amplitude. The vibrating body is then in *resonance* with the exciting force.

Any body which vibrates freely when the exciting force is removed illustrates free vibration, *i.e.*, a weight vibrating on a spring. Free vibrations, as such, are not important in vibration prevention. Forced vibrations give trouble if an exciting stimulus is present. Resonant types, where the exciting force is in step with the free vibration period, are the most difficult. Knowledge of free vibration period thus is important. An example of a forced vibration is an unbalanced rotor which quivers at all speeds, due to unbalanced centrifugal force; the frequency always equals the speed frequency. If speed is in step with the free vibration frequency of the rotor between bearings, vibration will reach a peak value, and illustrate resonance. All critical speed vibrations are resonant. Calculation of critical speeds is the determination of free vibration periods to which the body resonates.

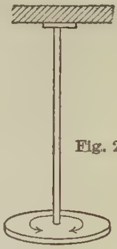

Fig. 2.

## 1. VIBRATION FREQUENCY CALCULATION

The following simple cases of calculation of natural vibration frequency are given for reference. Two basic formulas are:

**Linear vibration** for spring supported weight (Fig. 1), $f = (1/2\pi)(\sqrt{kg/W}$ . . . [1]

**Torsional vibration** for disk on rod (Fig. 2), $f = (1/2\pi)\sqrt{L_1 g/I}$ . . . . . . [2]

where $f$ = frequency, cycles per sec.; $g$ = acceleration of gravity = 386 in. per sec.$^2$; $k$ = stiffness constant of spring = force required to stretch it to unit distance, lb. per in.; $L_1$ = same constant in torsion, or force required to twist spring or rod through 1 radian of arc, ft.-lb. per radian; $W$ = weight, lb.; $I$ = moment of inertia, lb.-in.$^2$ = $WR^2$; $W$ = weight of body, lb., executing torsional vibrations; $R$ = radius of gyration. Formula [1] is used more often than [2], as most problems involve linear, rather than torsional, vibrations.

Substituting the value of $g$ for the inch-pound-second system, [1] and [2] reduce to

**Linear vibrations.** $f = 3.13\sqrt{k/W}$ cycles per sec. . . . . . . . . . [3]

**Torsional vibrations.** $f = 3.13\sqrt{L_1/I}$ cycles per sec. . . . . . . . . . [4]

**GRAVITY DEFLECTION FORMULA.**—For a spring carrying a weight (Fig. 1) causing extension $d$ of the spring, elastic constant $k$ must equal $W/d$ = weight per unit deflection. Substituting this in [3],

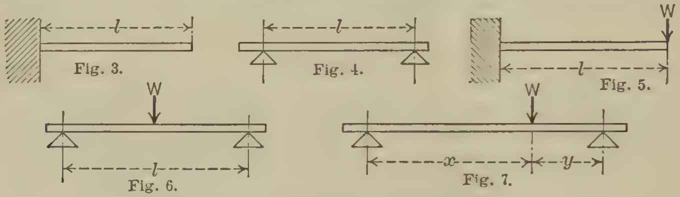
$$f = 3.13/\sqrt{d} \quad . . . . . . . . . . . [5]$$

where $f$ = cycles per sec.; $d$ = in. deflection. Thus if a weight causes an elastic support of relatively small weight to deflect downwards through $d$ in., [5] at once gives the up-and-down frequency. This formula is useful for quick, approximate estimates of certain vibration frequencies. Thus, a shaft carrying a relatively heavy fly-wheel has a deflection of $d$. The frequency and the critical speed (see p. 11-10) can be estimated, without knowing weight of the fly-wheel.

**VIBRATION OF UNIFORM BARS.**—For any vibrating bar of uniform cross-section, the frequency is given by

$$f = (k/l^2)(\sqrt{EI/w}) \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \quad [6]$$

where $k$ depends on shape of bar and how it is supported, and $l$ = length, in. For a cantilever bar (Fig. 3), $k = 11$; for a beam supported at the ends (Fig. 4), $k = 31$. Table 1 gives frequencies for circular and rectangular bars. In this table, $I$ = moment of inertia of cross-section, in.$^4$ (not mass moment of inertia); $w$ = weight, lb. per in.; $w_1$ = weight, lb. per cu. in.; $l$ = length, in.; $D$ = diam., in.; $h$ = depth, in., $E$ = modulus of elasticity.



Figs. 3–7. Vibration of Uniform Bars

**VIBRATION OF LOADED UNIFORM BARS.**—Table 2 gives frequencies of loaded bars, where weight of bar is neglected compared with weight it carries. Symbols have same meaning as in Table 1. These formulas are derived from [5] by substituting proper value of $d$ produced by a load $W$ for each case.

**VIBRATION OF CIRCULAR DISC OF UNIFORM THICKNESS SUPPORTED AT THE CENTER.** (Fig. 8.)—Such a plate has exactly the same vibration frequencies as one perfectly free; the formula is

$$f = K(h/r^2)\sqrt{(Eg/\rho)} \quad . \; . \; . \; . \; . \; . \; . \; . \; . \; . \quad [7]$$

where $h$ = thickness of disc, in.; $r$ = radius of disc, in.; $E$ = modulus of elasticity; $g$ = 386 in. per sec.$^2$; $\rho$ = density of disc material, lb. per cu. in.; $K$ = constant depending on the number of nodes $n$ along disc edge; when $n = 4$, $K = 0.25$; $n = 6$, $K = 0.54$. This assumes the absence of ring nodes, which case will be omitted.

## 2. VIBRATION MEASUREMENT

To measure vibration, frequency and amplitude must first be determined; without knowledge of these, quantitative study is impossible. Also, form of path described, *i.e.*, circular, elliptical, etc., and the phase relative to another vibration sometimes may be necessary.

**REED FREQUENCY METER.**—The most generally useful frequency meter is of Frahm tachometer type, Fig. 9. It comprises a series of reeds, fixed on a common base,

**Table 1.—Frequencies for Circular and Rectangular Bars.**

| | Uniform Bar, cycles per sec. | Circular Section, cycles per sec. | Rectangular Section, cycles per sec. |
|---|---|---|---|
| Cantilever (Fig. 3) | $11/l^2\sqrt{EI/w}$ | $(2.7\,D/l^2)(\sqrt{E/w_1})$ | $(3.18\,h/l^2)(\sqrt{E/w_1})$ |
| Beams supported at ends (Fig. 4) | $31/l^2\sqrt{EI/w}$ | $(7.7\,D/l^2)(\sqrt{E/w_1})$ | $(8.96\,h/l^2)(\sqrt{E/w_1})$ |

**Table 2.—Vibration of Loaded Uniform Bars.**

| Type of Loading | Frequencies, cycles per sec. | |
|---|---|---|
| | Circular cross-section | Rectangular cross-section |
| Loaded cantilever (Fig. 5) load on end | $1.2\,D^2\sqrt{E/W\,l^3}$ | $1.56\sqrt{E\,b\,h^3/W\,l^3}$ |
| Loaded beam (Fig. 6) loaded in center of span | $4.8\,D^2\sqrt{E/W\,l^3}$ | $6.24\sqrt{E\,b\,h^3/Wl^3}$ |
| Loaded beam (Fig. 7) load off center of span | $1.2\,D^2\sqrt{\frac{E\,l}{W\,x^2\,y^2}}$ | $1.56\sqrt{\frac{E\,b\,h^3\,l}{W\,x^2\,y^2}}$ |

carrying masses at their tips, and tuned to respond one after another over a range of frequencies. A convenient model about 6 in. long is made by Leeds and Northrup Co., Philadelphia, covering frequencies from 900 to 12,000 per min. by means of three instruments. It is easily portable, readily applied, and shows rapidly-varying frequencies as well as more than one frequency at a time if present. Above 12,000 cycles per min. (200 per sec.), sensitivity is lost due to stiffness of the reeds. For best response the meter should rest solidly against the vibrating body, direction of reed vibration being roughly parallel to direction of motion of exciting vibration. This instrument is an excellent substitute for speed counters and speed tachometers.

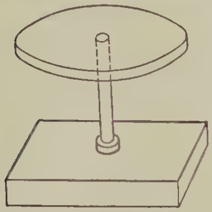


Fig. 8. Vibration of Circular Disc Supported at Center

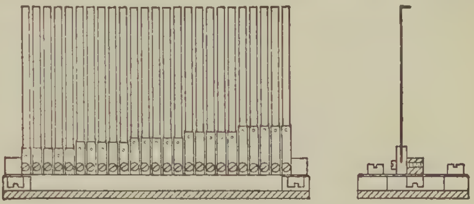

Fig. 9. Frahm Tachometer

**INERTIA AMPLITUDE INDICATOR.**—One form of instrument for amplitude measurement is the inertia type, Fig. 10. This is an ordinary Starrett dial strain gauge reading in mils, set in a hole in a block of metal weighing about 2 lb.; axis of indicator stem passes approximately through center of gravity of the block. The weight is so held that the indicator stem makes contact with the vibrating body, the metal block being kept free. The indicator stem oscillates with the vibrating body, but the weight to which the indicator body is set does not oscillate because of its inertia. If the vibrating body has an amplitude of, say, 3 mils in the direction of motion of the stem a blurred image 3 mils wide appears on the indicator dial scale. The scale numbering has no relation to the amplitude, which changes its position on the scale as the indicator is allowed to approach or recede from the vibrating body. If the indicator is held reasonably steady, the amplitude of the oscillation is easily read. This instrument is portable and easily applied, with the indicator stem pointing in any direction necessary to observe vibration amplitude. It is satisfactory for amplitudes of 10 mils or more for frequencies of ordinary rotating machinery. Precautions in using this instrument are: Avoid chattering of indicator button for frequencies over 100 per sec. with amplitudes of over 2 or 3 mils; for high frequencies the button may not follow the vibration if amplitude is too great. For frequencies below 5 per sec., the weight itself may vibrate and thus decrease indicated amplitude. In special cases, the amplitude indicator without the inertia part can be rigidly attached to a supporting post if a convenient point of attachment *free from vibration* is available.

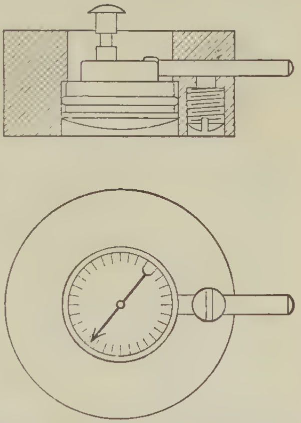

Fig. 10. Inertia Amplitude Indicator

**THE VIBROGRAPH** will make a complete graphical record of a vibration, giving a permanent record of both frequency and amplitude. A good instrument, made by Cambridge Instrument Co., traces the record by means of a fine stylus on moving celluloid film. It will easily record amplitudes under 0.5 mil, of frequencies over 100 per sec. The Geiger vibrograph is a well-known instrument which records with a pen on a moving strip of paper Both instruments are actuated by a spring-suspended mass on the seismograph principle. They are rather elaborate, with levers, etc., and lost motion must be compensated. For a more detailed description, see Vibration Problems in Engineering, S. Timoshenko, p. 327 *et seq.*, D. Van Nostrand Co. 1928.

**TORSIOGRAPH.**—To detect torsional oscillations in a revolving shaft, as a ship propeller shaft or a Diesel engine shaft, governed by a heavy fly-wheel, a Geiger or other torsiograph, should be used. This is an inertia instrument comprising essentially one part rigidly attached to the shaft, taking part in its torsional oscillations, and a fly-wheel, mounted in its own bearings and driven through a flexible spring at the shaft speed.

The fly-wheel maintains substantially constant angular velocity. A multiplying lever mechanism responds to shaft oscillations with respect to the non-oscillating fly-wheel, and records oscillations in a graph (see Timoshenko, *loc. cit.*). There is no satisfactory way of detecting torsional oscillations of a revolving body by such a simple device as used for linear vibrations of a stationary body. The avoidance of torsional oscillations of this character is very important, as many failures have been traced to torsional resonance involving excessive periodic stresses in shafting (see p. 16–11).

**ELECTROMAGNETIC METHODS.**—One type of electrical vibration measuring instrument records by motion of a pin placed against the vibrating body, registering in the same way that a loud speaker records oscillations on a phonograph record. This instrument can be made very sensitive to small amplitudes and high frequencies, as those producing sound radiation. Another instrument for lower frequencies and larger amplitudes, depends on the fluctuation of electrical impedance produced by air gap variation caused by the vibration, which in turn modulates the amplitude of a relatively high-frequency exciting electric current.

Both methods readily record frequency on the oscillograph, for example, but translation of electrical into mechanical amplitudes requires careful calibration over the frequency range, especially for lower frequencies. This usually is due to the spring applying the recording pin to the vibrating body being too stiff to deflect through full vibration amplitude. The author has encountered errors from this cause in this type of instrument. See Vibration Recorder, A. V. Mershon, *Trans.* A.I.E.E., 1926.

## 3. VIBRATION PREVENTION

Of the several methods of attack in vibration reduction, the particular method or methods adopted depend on the individual problem. Briefly these methods are:

**REMOVAL OF EXCITING CAUSE.**—This, when possible, is most satisfactory. Unbalance in rotating machinery is a common source of trouble. In rigid rotors it can be almost completely eliminated by balance weights. Gear tooth frequency noise is best avoided by precision in manufacture.

**TUNING** is applicable only when vibration is distinctly of resonant type. Resonant vibrations usually are excited by a relatively small stimulus, which happens to be in step with a natural vibration frequency. The tuning of steam turbine wheels is an example, also the avoidance of shaft critical speeds through selection of proper diameter at the operating speed.

**ELASTIC SUSPENSION.**—The function of elastic suspension is to *isolate* a powerful forced vibration so that it cannot be transmitted beyond the vibrating piece of apparatus. This is not a friction damping process. Springs do not absorb vibrations through damping, but are often a very effective means of preventing transmission; *e.g.*, the spring suspension of a railroad car isolates from the car body forced vibration imparted to the wheels; the leaf spring contains some friction damping which eliminates resonant bouncing, but has no part in isolation. It can be shown that such friction in springs and shock absorbers somewhat increases forced vibration transmission. The amount of increase is small, even when friction is considerable. Friction is necessary to avoid building up resonant vibrations.

Elastic suspension methods are much used to suspend noisy machinery, etc., but there is still much guesswork in their application. An incorrectly designed elastic suspension may do more harm than good. The design of a good suspension is not always an easy matter and often requires knowledge of vibration principles as well as experience.

**DAMPING,** or reduction of vibration amplitude through action of friction, is a cure for resonant vibrations only. Forced vibrations are apt to result from powerful exciting forces which are not much reduced by application of friction devices. For example, gear tooth frequency hum or whistle is a forced vibration, which is reduced but little by stuffing the wheel with a non-resonant damping substance with internal friction. On the other hand the resonant ring of the wheel due to its natural periods, may be greatly reduced by such treatment. Shock absorbers used in vehicle suspension are typical friction dampers which limit the amplitude of resonant vibrations excited by road irregularities.

### Removal of Exciting Force

**MECHANICAL BALANCE OF MACHINERY.**—It is possible to completely mechanically balance any rigid rotor, whatever be its unbalance or its shape, by only two weights. The problem is to determine the position and the size of these two weights. Balancing is a fine art, and trial-and-error methods by a clever mechanic generally will waste money.

**STATIC AND DYNAMIC BALANCE.**—Mechanical unbalance in a rigid rotor always can be completely represented schematically as in Fig. 11. The weight $A$ takes account of displacement of the center of gravity of the rotor from its axis; weights *B* and *C* represent a couple, depending on how much the rotor is cocked or twisted sideways from its true axis. The three weights can be replaced by two by splitting *A* into two parts, placing one in the plane of *B* and the other in the plane of *C*. The two weights in each of these planes then can be replaced by a single one in each plane by applying the parallelogram of forces (centrifugal forces in this case). See A. L. Kimball, Vibration Prevention in Engineering, pp. 85–94 (John Wiley & Sons, Inc., 1933) and S. Timoshenko, Vibration Problems in Engineering, p. 157 *et seq.* (Van Nostrand). That part of unbalance represented by *A*, Fig. 11, is *static unbalance*; it can be detected by a static or gravity test by placing the rotor on ways and noting its heavy spot. The part represented by weights *B* and *C* is *dynamic unbalance*; it can be detected only by a rotational or dynamic test which develops a centrifugal couple. A rotational test, however, does not separate dynamic from static unbalance, but combines the effect of both; otherwise, mechanical balance would be comparatively simple. For this reason, specially designed machines and special methods, described below, must be used to determine the amount and position of balance weights.

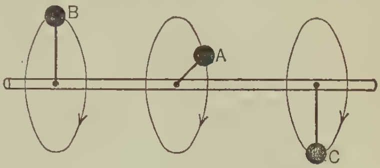

Fig. 11. Mechanical Unbalance

**BALANCING MACHINES.**—For large production, some type of good balancing machine is essential. Many are unsatisfactory. A good machine is the Precision balancing machine built by the Gisholt Mfg. Co. Another widely used German machine built by Karl Schenk, the Lawaczeck-Heymann machine, is fairly satisfactory for rotors of 500 lb. and up, and is less expensive than the former. The Precision machine has proved itself of particular value in balancing automobile crankshafts. E. L. Thearle (General Electric Co.) has produced the best balancing machines in existence for that company's type of work; these have not been sold outside to any extent (1933). Tinius Olsen Co. has produced a very good machine for small rotors.

Balancing is a highly specialized art. Different balancing problems require different machines, designed for the particular conditions to be met. Only large and fairly uniform production justifies the design and purchase of such a machine.

## Balancing of Special Jobs

**SMALL RIGID ROTORS.**—The following method of balancing small rigid rotors gives good results, with a minimum of apparatus. The rotor, *R*, Fig. 12, is placed in a light wood frame *F*, resting in half bearings in the frame, and driven by motor *M* through belt *L*, whose tension is adjusted by screw *S*. The rotor is first pivoted in plane *C*, the pivots in plane *D* being withdrawn. A spring, not shown, is placed under the frame at bearing *B*, of sufficient stiffness to cause resonance at 700 to 800 r.p.m. The rotor being driven through the resonant frequency, the deflection indicator *E* is adjusted with its button resting on top of the frame to register vibration. The arc through which the needle oscillates approximately measures unbalanced moment about fulcrum in plane *C*.

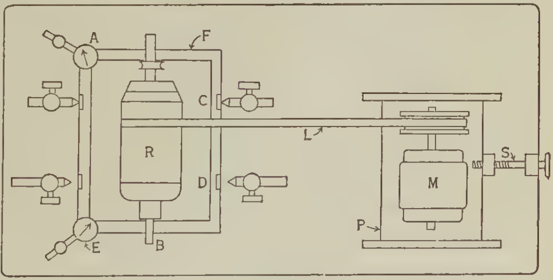

Fig. 12. Balancing Set

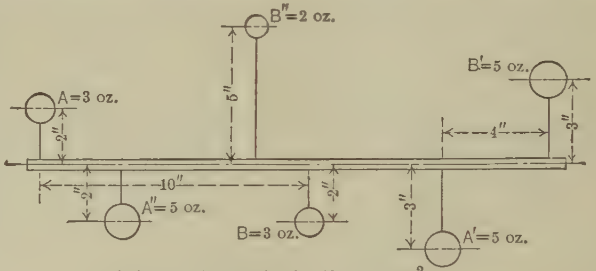
To find amount and position of the weight, vibration amplitude is read and a small trial weight successively placed in four positions 90° apart in plane *D*; the amplitude of vibration is read in each case. A curve of rise and fall of amplitude is plotted against angular position of trial weight, from which amount and position of weight can be estimated. Inspection of the curve shows position where weight subtracts most from the unbalance and adds most to it; the former is the correct position of balance weight. Its amount is estimated by comparing change of vibration amplitude produced by the weight in different positions with the original vibration amplitude, assuming vibration amplitude to be a direct measure of weight required. The trial weight for small rotors may be a piece of wax.

Besides having a light frame to insure large amplitudes, the outfit must not vibrate as a whole due to insecure foundation; it must be placed where no floor vibrations are transmitted to it, otherwise indicator readings will be inconsistent. Furthermore, the frame must be sufficiently stiff to resist all tendency to flexure. A good way to isolate the apparatus from such vibrations and prevent detrimental shaking is to place the outfit on a massive iron plate resting on toy rubber balls or an inflated automobile inner tube. The driving motor must be well balanced, and a light belt used to give a constant tension perpendicular to the oscillatory motion of the frame; the pull should not be too great. To balance the other end of the rotor, the process is repeated, using the other fulcrum. Weights so determined should produce complete balance so that the indicators show no oscillatory motion.

**AIRPLANE PROPELLER** unbalance may be made up of unbalanced air reaction and mass unbalance. If one blade exerts slightly greater traction on the air than the other, an unbalanced couple is present which revolves with the propeller, always tending to deflect the forward end of the propeller shaft towards the blade exerting the smaller traction, thus causing the engine to wobble. Since traction on one propeller blade is several hundred pounds, any dissymmetry between blades, either of shape or pitch, produces a relatively large unbalanced couple, and aerodynamic unbalance may far exceed pure mechanical unbalance. Hence, extremely precise mass balance of airplane propellers may be disappointing. Little systematic study has been made of this problem, and quantitative data are lacking; the slighest change in pitch of a blade noticeably affects plane vibration. The problem is complicated by blade deflections during operation which must react on the traction. Propellers of high power planes are subject to severe engine torque pulsations with resulting vibration, but the exciting force comes from the engine.



Unbalanced Couple=3 x 2 x 10=60 oz.-in.$^2$
I. Balancing Couple=5 x 3 x 4 = 60 oz.-in.$^2$
II. Balancing Couple=2 x 5 x 6 = 60 oz.-in.$^2$ or 5 x 2 x 6=60 oz.-in.$^2$

FIG. 13. Methods of Balancing Centrifugal Couple

**RULES FOR DESIGN.**—A good rule for design of rotating apparatus with moving parts, where unbalanced forces are present, is to keep the center of gravity of the complete moving system as nearly as possible on the rotation axis for all positions of the shaft as it revolves. Next, estimate as nearly as possible, the centrifugal couple which remains (weights $B$ and $C$, Fig. 11) and place *anywhere* on the shaft a pair of weights to produce a counteracting couple. Fig. 13 shows two possible ways of balancing a centrifugal couple produced by weights $A$ and $B$ in one plane, namely, by $A'$, $B'$, or by $A''$, $B''$. Note that the pair of weights may be placed anywhere in this plane along the shaft if the couple produced is equal and opposite in magnitude to that of the original weights. The couple in each case is measured by the product of either one of the two weights times its distance from the shaft times its distance along the shaft to the second weight of the pair. The two weights do not have to be equal, but the products (magnitude of a weight × distance to shaft axis) must be equal. The use of unequal weights and axial distances is shown where the pair $A'' + B''$ are counterweights.

**WORKMANSHIP.**—In symmetrical rotors with perfect workmanship and materials, there should be no unbalance. For a $^1/_2$-Hp., 1800 r.p.m. motor, for example, an unbalanced weight of 0.05 oz. will produce appreciable vibration of say 2 mils amplitude. So small an unbalance cannot be avoided by ordinary shop processes, even with the best supervision. It is cheaper to manufacture rapidly and balance later.

**MEASUREMENT OF AMOUNT OF UNBALANCE.**—It is sometimes necessary to form a quick estimate of the amount of unbalance in a machine. To measure this in an electric motor, place it on rubber pads which should compress at least $^1/_8$ in. under the motor at usual speeds. Maximum vibration amplitude in a direction transverse to shaft is an approximate measure of the amount of unbalance. This is best determined by an inertia amplitude indicator, Fig. 10. The suspension must be at least as yielding as specified, otherwise the vibration produced will be either too small or greatly amplified through resonance.

Another form of suspension used by the author to estimate unbalance is to hang the motor by a relatively long spring through straps or a *light* cradle, preferably of wood, to reduce inertia. Weight of the motor should stretch the spring perceptibly. Vibration amplitude is measured as before by amplitude indicator. This method offers less restraint to the vibrating body than mounting on rubber pads.

The object of this test is to find how unbalanced apparatus vibrates when unrestrained by outside forces. The exciting stimulus acts almost entirely against the inertia of the body itself, and oscillations produced are proportional in amplitude to the exciting force.

In single-phase motors, a vibration of considerable intensity may be present, due to a torque pulsation of twice the alternating current frequency, *i.e.*, 120 cycles per sec. for a 60-cycle circuit (see Single-phase Motor Torque Pulsations, Kimball and Alger, *Trans.* A.I.E.E., 1924, p. 730). This frequency is much higher than ordinary rotation speeds, and thus much higher than vibration from unbalance which is always in step with r.p.m. frequency. It shows up well with the above suspensions. It is easily separated because of its higher frequency, and its causing the motor to oscillate about the shaft as a stationary axis. Mechanical balance will not cure this electrical vibration.

Motor hums from electrical causes mostly are eliminated by elastic suspension. See p. 16–16. By these methods it is possible to quickly select the best balanced among a number of similar motors, if means for balancing are not available.

**ELIMINATION OF SELF-INDUCED VIBRATIONS.**—A troublesome type of vibration that occurs in rotating machinery operating above the critical speed is termed *self-induced vibration.* Its frequency is always the same as the critical speed frequency, which may be lower than the r.p.m. frequency of the shaft in the same way that the revolution frequency of the earth around the sun is much lower than its rotation frequency about its axis.

**Whirling Due to Oil Action in Journal Bearings.**—This type of self-induced vibration arises only when the rotation of the machine is more than twice the critical speed frequency. It is produced by wedges of oil driving the journal around in the bearing and exciting a whirl. If a well-balanced machine tends to unstable operation, and vibration appears when the rotation frequency is more than twice the critical speed, this kind of whirl is the probable cause. The best method of elimination is to insure that the critical speed frequency is more than half the r.p.m. frequency of the shaft. Another remedy, in smaller rotors, is to replace journal bearings by ball bearings.

**Whirling Due to Frictional Action within the Rotor.**—Any rotor with self-contained friction, produced by flexure while revolving, will build up a whirl at any rotational speed higher than the critical. Friction of this type may be produced by rings so shrunk on a shaft that working may occur between the bore of the rings and the surface of the shaft. Frictional working also can arise in laminated structures, carried by the shaft, which structures flex and rotate at the same time.

These phenomena usually occur in motors with flexible shafts which operate far above the critical speed, and in such devices as extractor type washing machines, which contain rotating parts operating well above the lower critical speed.

## 4. VIBRATION ELIMINATION THROUGH TUNING

### Shaft Whirling

**CRITICAL SPEEDS.**—When a shaft or rotor, revolving in bearings, speeds up to where centrifugal force tending to whip it sideways just balances the elastic stiffness tending to keep it straight, the slightest mechanical unbalance builds up a whirling motion, which may be of destructive amplitude. The rotor then is revolving at a *critical speed.* It is inadvisable to run any rotor or shaft at or near critical speed for any length of time, regardless of perfection of balance. Critical speeds usually are avoided by designing the rotor shaft sufficiently stiff to hold its operating speed well below its critical speed. This sometimes is impossible for very heavy or very high speed rotors of long span between bearings. The shaft then is made sufficiently flexible to insure operation well above critical speed. This practice is to be avoided if possible, as vibration may develop from other causes in operation above critical speeds, although, so far as unbalance is concerned, operation is stable except close to critical speed.

**CRITICAL SPEED CALCULATION.**—Critical speeds of a rotor are almost identical with natural vibration frequencies which the stationary rotor may assume.

**Uniform Shaft.**—The first critical speed is given by the formula

$$7.7(d/l^2)\sqrt{E/w_1} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [8],$$

where $f$ = critical frequency, cycles per sec.; $d$ = shaft diameter, in.; $l$ = span between bearings, in.; $E$ = modulus of elasticity shaft material; $w_1$ = weight of 1 cu. in. of shaft material, lb. This formula is given in Table 1, for a circular bar vibrating between two end supports. For steel, the formula becomes $f = 7900\ d/l^2$ . . . . . . . . . . [9]

At the first critical speed, the shaft whirls in one loop with nodes at the bearings; at second critical speed, in two loops with a node in the middle, at 4 times the first speed; at third critical speed, in three loops at 9 times the first critical speed, etc. Upper critical speeds, which enter only in high-speed installations, are special problems in themselves.

**Shafts with Concentrated Loads.**—A useful approximate formula derived by Dunkerley from analysis, checked by careful tests on models, for a uniform shaft carrying concentrated loads, Fig. 14, is

$$1/f^2 = 1/f_s^2 + 1/f_1^2 + 1/f_2^2, \text{ etc.}, \qquad [10]$$

where $f$ is critical frequency of the whole system; $f_s$ that of shaft *by itself* as calculated from [8]; $f_1$ that of shaft considered as weightless, with load $W_1$ by itself, given by the last formula in column 1 of Table 2, etc., for the other concentrated loads. It is evident that values for $x$ and $y$ in the latter formula depend on location of $W_1$, $W_2$, etc., on the shaft. Quantities are in., lb. and sec. This formula should not be used for 3-bearing sets.

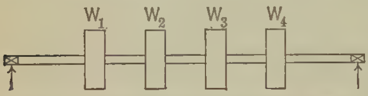


FIG. 14. Shaft with Concentrated Loads

**Shaft of Varying Cross-section and Load.**—When cross-section of shaft is not uniform, and the load is distributed along it, as in most rotors, the problem is not so simple. It can be approximately solved from knowledge of the static load-deflection curve, as vibration frequency calculated on the basis of this deflection curve is only slightly higher than that based on the true deflection curve for actual vibration.

When static deflection curve is known, vibration frequency or critical speed frequency easily is calculated from

$$f = 3.13\sqrt{\frac{W_1 y_1 + W_2 y_2 + W_3 y_3 + \text{etc.}}{W_1 y_1^2 + W_2 y_2^2 + W_3 y_3^2 + \text{etc.}}} \qquad [11]$$

where shaft and rotor are divided into a series of slices of convenient length of weight $W_1$, $W_2$, etc. (including loads), and corresponding deflections $y_1$, $y_2$, etc. See Fig. 15. All quantities are in., lb. and sec. The problem is primarily one of static deflection curve determination, which, in cases similar to Fig. 15, requires using graphical statics. For the solution of such a problem, see Timoshenko, Vibration Problems in Engineering.

**Three-bearing Sets.**—A 3-bearing problem can be solved by formula [11]; both first and second critical speeds should be found, as they may not lie far apart, while the second critical of a rotor with only one span will be at least twice the first. At the first critical speed of a 3-bearing set, one span deflects upward when the other deflects downward; in finding static deflection curve, loads on one span must be taken as acting upwards. Deflection of one span influences that of the other through a bending moment across the middle bearing. The deflection curve determination must take account of this. The second critical speed occurs at a somewhat higher frequency where both spans deflect in the same direction, with a point of inflection in the shaft near the middle bearing. The static deflection curve then is found from loads all acting in one direction, but again, bending moment is transmitted across the middle bearing. The best procedure for this special problem is to refer to more advanced treatments noted in preceding paragraph.

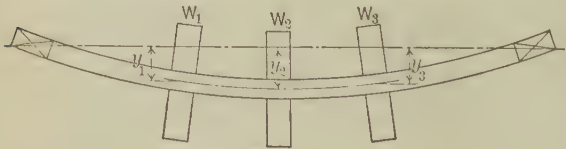

FIG. 15

**BEARING ELASTICITY.**—All critical speeds are actually somewhat lower than calculation indicates, as no bearing is perfectly rigid. Also, up-and-down stiffness of a bearing is apt to be much greater than its sidewise stiffness. Due to this, two critical speeds may be present; one involves an elliptical whirl where the motion is mostly up and down; the other, at a speed a few percent lower is sidewise elliptical motion. The lower frequency results from greater sideways elastic yielding of the bearings. For very heavy rotors, critical speed may be 30% lower than calculated for rigid bearings.

**ELLIPTICAL SHAFTS.**—If a shaft is not circular, but elliptical or flattened on opposite sides, being stiffer in one axial plane than in one 90° away, bad performance must be expected in operation near critical speed. The rotor evidently will vibrate in one plane at a somewhat lower frequency than in the plane for which it is stiffer. In an ideal case, with no damping, operation is unstable between these two frequencies. A model shaft and fly-wheel, with the shaft flattened on two sides vibrates violently near the critical speed, and must be restricted by a guard ring. Rotors which perform badly near the critical speed are open to suspicion of being built stiffer in one plane than another.

**TORSIONAL VIBRATION OF LOADED SHAFTS.**—Critical torsional vibration frequencies as well as transverse criticals may occur in shafts carrying fly-wheels, and subject to periodic torque impulses, such as occur in Diesel engines. Torsional critical speeds are more insidious than transverse, as they are not evidenced in operation by excessive vibration, as are the transverse criticals. Since dissipation is small, operation on a torsional critical speed causes large torsional stresses which often result in fatigue failure.

Loaded shafts only are treated below. Torsional inertia of shaft itself is neglected, as it usually is small. This cannot be done in all cases, but in many problems nearly all torsional inertia is concentrated in certain planes, as in shafts carrying fly-wheels and crank-shafts. See Tulpin, Torsional Vibration (John Wiley & Sons) and Wilson, Practical Solution of Torsional Vibration Problems (Wiley).

**SHAFT CARRYING THREE FLY-WHEELS.**—Fig. 16 shows a shaft carrying 3 fly-wheels, one of which may be the equivalent of a crank-shaft. This system has two critical frequencies, given by the expression

$$f = 3.13\sqrt{(-B \pm \sqrt{B^2 - 4AC})/2A} \quad . \quad . \quad . \quad . \quad . \quad . \quad [12]$$

where $A = (I_1 I_2 I_3)/(k_1 k_2)$; $B = -[\{(I_1 I_2 + I_1 I_3)/k_1\} + \{(I_2 I_3 + I_1 I_3)/k_2\}]$; $C = I_1 + I_2 + I_3$; $I_1, I_2, I_3$ = moments of inertia of the three fly-wheels; $k_1, k_2$ = torsional elastic constants of the two shaft lengths between the fly-wheels, in.-lb. per radian of twist.

For a disc-shaped fly-wheel of weight $W$ lb. and radius $r$ in.,

$$I = (Wr^2/2) \text{ lb.-in.}^2 \quad . \quad . \quad . \quad . \quad . \quad [13]$$

If the shafting which spans distance between two fly-wheels is of uniform diameter, for a given span

$$k = \pi N a^4/2l \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [14]$$

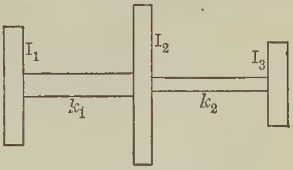

Fig. 16. Shaft Carrying Three Fly-wheels

where $N$ = rigidity or shear modulus of shaft material; $a$ = shaft radius, in.; $l$ = length of span, in. The lower of the two frequencies given by [12] is that for which the inside radical is negative. The first and last fly-wheels vibrate in opposite phase with a node somewhere between. If the system is made up of three identical fly-wheels connected by two identical spans the node is exactly at the middle fly-wheel, which remains stationary while the two end ones vibrate against each other. For the upper of the two frequencies, the end fly-wheels vibrate in phase; the middle one is in phase opposition, with a node somewhere along each connecting shaft length, making two nodes in all. No more resonant frequencies are possible with this system.

**SHAFT WITH ONE FLY-WHEEL AT EACH END** is solved by formulas [12], [13] and [14], where $I_3 = 0$, in which case [12] reduces to the simple form,

$$f = 3.13\sqrt{(I_1 + I_3)k/I_1 I_3} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [15]$$

where $k = k_1 k_2/(k_1 + k_2)$. This system contains one resonant frequency. Torsional elastic constants $k_1$ and $k_2$ are calculated by [14] for shaft sections of uniform diameter as before, where $l_1$ and $l_2$ are lengths of the two shaft sections, and all quantities are in in.-lb.-sec. system. If the shaft is of uniform diameter from $I_1$ to $I_3$, the constant $k$ can be directly found by [14].

**DESIGN CONSIDERATIONS.**—The torsional stiffness of shaft and inertia loads must be such that none of the calculated natural frequencies is in step with any periodic impulse from the driving engine. An engine with several cylinders will produce several torque impulses per revolution. If, for example, 12 torque impulses per second are present at operating speed, there are also present $^{12}/_{2}$, $^{12}/_{3}$, $^{12}/_{4}$, $^{12}/_{6}$, $^{12}/_{12}$ that is, 6, 4, 3, 2 and 1 impulses per second, as well as 12, which may excite resonance. Safety requires the system to be so stiff that all its critical frequencies are above the highest torsional impulse frequency. No resonance then can be built up. This is particularly necessary in the massive systems used with Diesel engines. Friction devices sometimes are used for smaller engines, whereby one or more inertia parts are permitted to turn on the shaft against friction clamps; when torsional oscillations develop, the clamps damp them out. Friction devices of this kind often give trouble.

Most actual cases cannot be treated by the simple analysis given above, because of varying shaft sections or the presence of more than three inertia parts, etc. For more complicated problems in this field, as automobile crank-shaft design, see Timoshenko, Vibration Problems in Engineering; Root, Dynamics of Engine and Crank-shaft Design (John Wiley & Sons). An understanding of general principles, however, should enable a designer intelligently to approach problems of this kind, and to guard against vibration.

**TURBINE WHEEL VIBRATION. Cause.**—The edge or periphery of an elastic disc will transmit a train of flexural waves around it at a characteristic speed determined by mass per unit area and stiffness of the disc. As the boundary of the disc has a finite circumferential length, the wave lengths must have certain fixed values; *e.g.*, the disc edge may carry a continuous train of 2, 4, 6 or 8, etc., waves, whose wave length is $^1/_2$, $^1/_4$, $^1/_6$, $^1/_8$, etc., of the disc circumference. Each wave train has a different velocity, longer wave lengths moving at considerably higher speeds than shorter. In a disc of uniform thickness, supported at the center, wave speed, rev. per sec., can be calculated by

$$\text{rev. per sec.} = [K(h/r^2)\sqrt{Eg/\rho}]/2n \quad . \; . \; . \; . \; . \; . \; . \; [16]$$

where $K$ depends on $n$, the number of nodal points along the disc edge; for values of $K$ and meanings of symbols, see p. 16–04.

Turbine wheels are not of uniform thickness, and must be calculated by special methods. For detailed discussion of turbine wheel vibration and design, see W. Campbell, Protection of Steam Turbine Disc Wheels from Axial Vibration, *Trans.* A.S.M.E., vol. xlvi, p. 31, 1924.

Critical speeds exist for turbine wheels at which operation is hazardous; large wheels have several such speeds. These critical speeds are equal to the several wave train speeds given by [16] except for a correction necessary due to stiffening effect of centrifugal force, which makes wave speeds for a revolving wheel somewhat higher than those given by [16] for a stationary wheel. See Campbell's paper noted above.

When a turbine wheel runs at one of its criticals, the wave train at whose speed the wheel revolves will be stationary in space, because the wave train moves backwards in the wheel at same speed that the wheel turns forward. A small axial pressure on the wave zone of the wheel near its outer edge, *i.e.*, the bucket zone, may sustain and build up such a standing wave train. Thus only the wave train moving backward in the wheel is built up, but the corresponding forward moving wave train is not maintained.

Long waves, corresponding to 4 or 6 radial nodes, build up more easily than wave trains of shorter wave length. Large, relatively thin wheels are more susceptible to wave-building action due to the greater area on which steam acts, and their greater flexibility, permitting small initial disturbances from which wave trains build up to be more easily excited. For the same reason large-amplitude waves build up easily, with resulting fatigue failures of disc material.

**Prevention.**—The two-fold remedy is: 1. Design the wheels to avoid operation at all critical speeds or wave train speeds. For small turbines, this usually can be done; with large wheels it is not practical for the highest speed wave train, unless the wheels are excessively heavy. Next best is to place operating speed half way between that of the 4-node and 6-node wave train. 2. Do not depend too much on avoiding criticals, but keep the buckets and wheels sufficiently stiff, based on past successful operation.

**Precautions.**—It is not safe to depend on calculation alone. Measured frequencies, from which critical speeds can be calculated, may diverge 10% from the best calculations, due to initial stresses in the disc itself, or to cramping of buckets. A hoop tension or compression along the outer zone of the disc will alter frequency materially. For details see Campbell's paper above noted.

**GEAR WHEEL VIBRATIONS. Torsional Oscillations in Gear Trains.**—Fig. 17, illustrates a system of gears and fly-wheels, subject to torsional oscillation. The two frequencies of this system are best calculated by reducing to a system equivalent to Fig. 16, by replacing $I_1$ and $K_1$, Fig. 17, by $I_1'$ and $K_1'$, where $I_1' = n^2 I_1$ and $K_1' = n^2 K_1$, $n$ being gear ratio. The inertia of the pinion has been neglected. If moment of inertia $I_2$ of the gear wheel is small compared with $I_1$ and $I_3$ of the fly-wheels, $I_2$ may be taken as zero. There then is but one resonant frequency, found by

$$f = \sqrt{\{(I_1' + I_3)/I_1'I_3\}\{K_1'K_2/(K_1' + K_2)\}} \quad . \; . \; . \; . \; . \; [17]$$

It is remarkable that in this case the pair of gears gives the same frequency that would obtain if the shafts were fixed end to end with no gears between, regardless of value of gear ratio $n$. This can be checked by substituting $I = I'/n^2$ and $K = K'/n^2$ in [17], and comparing with result obtained when $I'$ and $K'$ are used. The relative vibration *amplitudes*, however, depend directly on $n$; that is, in Fig. 17, when gear train is present, for a given oscillation amplitude of $I_3$, that of $I_1$ is $1/n$ times its value for the shafts direct connected without the intermediate gears. For more than one pair of gears the problem is more complex. See Timoshenko, Vibration Problems in Engineering, p. 154, for a mathematical analysis of this problem.

**Vibration of Gears Due to Impact.**—Practically all gears produce a hum of gear tooth frequency, which in high-speed gearing under load, may be very penetrating. This is primarily a forced vibration, and will be little helped by tuning. The only sure cure is precision of manufacture, together with a design which permits of perfectly constant angular velocity for all tooth positions. Sometimes a resonant ring in gear wheels also is present. This type of noise can be largely eliminated by methods given under head of vibration damping. See p. 16–17.

**VIBRATION OF STRUCTURES.**—All structures and buildings are subject to resonant vibrations of several frequencies; the lower frequencies arise from a swinging of the whole structure; the higher are due to vibrations of component parts. The best way to eliminate such vibrations, when set up by a periodic force of known frequency, is some method of tuning.

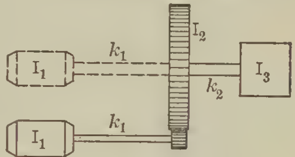

FIG. 17. Torsional Oscillation in Gear Train

**FOUNDATION VIBRATIONS OF MACHINERY.**—Foundations of heavy machinery may be structures of considerable size. Sidewise and up-and-down frequencies in a steam turbine should be roughly estimated in design and compared with the revolution frequency, or, for other types of machinery, with the predominant exciting frequency. Accurate calculations of frequencies of such structures are not worth while, due to their complexity, unless a thorough study is contemplated. Rough estimates based on common-sense application of vibration principles give almost as reliable results as more refined calculations.

The method of procedure is: Reduce the system to a single lumped mass vibrating against single stiffness constants, one for up-and-down motion, one for sidewise motion, etc., and use formula [3]. For example, a structure, Fig. 18, carries rotating machinery of weight $W_1$. The total weight used to calculate up-and-down vibration frequency includes, say, half the structure floor, as only the middle portions vibrate up-and-down to any extent. For sidewise vibration, the total floor weight and part of the columns is included, as the whole floor and column tops move through approximately full amplitude. Constant $K$ is found in each case by estimating the downward force on the platform and the sidewise force, respectively, in pounds required to produce 1 in. of deflection. This requires some ingenuity, but with a little practice it is not difficult for an approximate result. Frequency depends on the square root of mass and stiffness, and error is minimized in the final result.

Even if the principal modes of vibration have frequencies a safe distance from the operating frequencies, individual parts of the structure may resonate, especially when built of steel members. To cure resonance of individual members, stiffen or load them in different ways until vibration disappears. This usually is not difficult. It evidently is impractical to attempt to predetermine frequencies of *all* the individual members of such a structure.

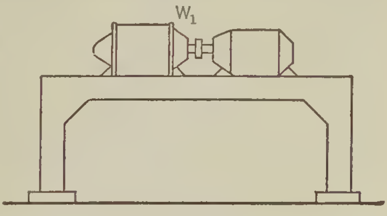

FIG. 18

**BUILDING VIBRATIONS.**—Ordinary buildings have sidewise natural frequencies of 2 or 3 per sec., as is clearly shown during slight earthquakes, or when delicate apparatus is being mounted.

**GROUND VIBRATIONS.**—Heavy machinery causes local vibration of its foundation, and also at times earth waves radiating in all directions to a considerable distance. If the foundation rests on bed rock, such transmission is negligible; with a foundation on clay or sand, and a periodic force of high intensity and low frequency, surface waves can be detected $1/2$ mile or more away in clay or sand beds. Ground waves may be avoided by placing heavy machinery foundations on bed rock, and by avoiding clay or sand flats, as well as unbalanced exciting forces. Bed rock, however, transmits higher frequency, objectionable sound vibrations better than clay.

**RESONANCE IN HELICAL SPRINGS.**—Helical springs subject to periodic compression and extension, as automobile valve springs, may resonate badly, with resulting fatigue failures. Longitudinal resonant frequencies in helical springs fixed at each end are calculated with considerable precision by

$$f = (n/2\,l)\sqrt{k\,g/w} = (9.8\,n/l)\sqrt{k/w} \quad . \; . \; . \; . \; . \; . \; . \; . \quad [18]$$

where $n$ = number of half waves between fixed ends; $l$ = length of spring, in.; $w$ = weight per in. of axial length, lb.; $k$ = elastic constant of spring *per unit length, i.e.*, force, lb., necessary to double the length of spring; $f$ = cycles per sec. Thus the lowest frequency, where $n = 1$, corresponds to $^1/_2$ wave between ends; the next, where $n = 2$, to two half-waves, etc. See Fig. 19. To avoid these resonances, the spring must be so designed that none of these frequencies are in the operating range. If possible, its stiffness should be such that the lowest resonant frequency for which $n = 1$ is above the operating range of frequencies.

**SHIP VIBRATION.**—Hulls of ships, particularly steel ships, are subject to resonant vibrations. A long ship has several resonant frequencies in which flexural vibrations of the ship as a whole occur, with two or more transverse nodal lines. These frequencies can be calculated approximately, and should not be in step with exciting forces. The principal periodic exciting force to be avoided is propeller blade frequency, *i.e.*, rev. per sec. × number of blades. This force comes from a periodic reaction of water from the propeller on parts of the stern, which is difficult completely to eliminate. Such a condition of resonance may be tuned out to a large extent by altering cargo distribution, thus altering natural frequency.

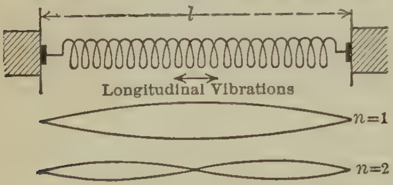

FIG. 19

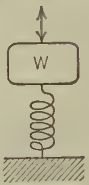

FIG. 20

## 5. VIBRATION REDUCTION BY ISOLATION

### Forced Vibrations

Forced vibrations may be cured by resorting to *isolation*; they do not yield readily to damping and cannot be tuned out. The standard method of isolation is to use an elastic suspension.

**ELASTIC SUSPENSIONS** function through ability to reduce the periodic force reaction of a vibrating body on its support. Fig. 20 shows the simplest possible spring suspension, where a weight $W$, with an up-and-down forced vibration of frequency $f$ imposed on it, is supported by a vertical spring. Transmissibility of such a spring support is given by

$$\text{Transmissibility} = \epsilon = f_0^2/(f^2 - f_0^2) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [19]$$

where $f_0$ is natural or resonant up-and-down frequency of spring support as given by [3] and [5]. *Transmissibility* may be defined as the ratio of vibration forces *actually* transmitted to those which *would* be transmitted without spring suspension. Thus, to be of use, $\epsilon$ must be less than unity; experience shows that in most cases to be really effective $\epsilon$ should be as small as $^1/_{30}$ to $^1/_{40}$. This means that $f_0$ should be from $^1/_5\,f$ to $^1/_6\,f$. Fig. 21 shows a graph of [19] as dependent on $f/f_0 = r$.

**PRECAUTIONS IN USE OF ELASTIC SUSPENSIONS.**—All elastic suspensions necessarily have their own resonances. Thus if a suspension is designed to isolate a frequency of $f$ = 120 cycles per sec. with a resonant frequency $f_0$ = 30 cycles per sec., it must be certain that no 30-cycle exciting frequency is present in addition to the 120-cycle. This is especially true for rotating machinery, whose rotation speed is usually in that field. Fig. 21 shows that transmissibility is greater than unity when $f$ approaches $f_0$, and may be very large near resonance. Furthermore, $\epsilon$ is always greater than unity when $f$ is less than $f_0$. Nearly all elastic suspensions have resonance frequencies other than $f_0$ corresponding to the particular mode of vibration for which they are designed. This must be considered in design.

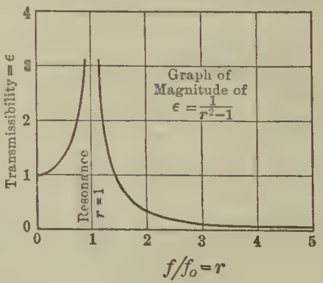

FIG. 21

Elastic suspensions do not damp a vibration by friction, but prevent transmission by power to isolate. Contrary to general belief, damping *increases* transmissibility, although the increase is small with a moderate amount of damping. See Kimball, Vibration Prevention in Engineering, pp. 96–107. A moderate amount of damping is of advantage as it safeguards against excessive vibration near resonance, but not because it improves isolation.

The following facts should be considered in design, including the best material to use. Cut-and-try methods will, in the long run, be costly; elastic pads of too large area in proportion to their thickness do not yield enough under gravity to isolate other than high frequencies. See formula [5] for frequency calculation from gravity deflection $d$.

**ELASTIC SUSPENSION MATERIALS.**—Steel, rubber, cork and gelatin compounds commonly are used for spring suspensions.

**Steel** has the advantage of being very durable. It contains practically no damping, and therefore is subject to possible resonances to other exciting forces than the one being screened.

**Rubber** is more flexible than steel from the design standpoint. See discussion of elastic suspension of motors, p. 16–16. It has some damping. To avoid age-hardening, only the highest grade, produced for this special purpose, should be used. Long life then is possible, even under severe conditions. Rubber should not be loaded more heavily than 50 lb. per sq. in. It is very incompressible, and yields almost entirely through shear. In designing rubber supports, space for elastic flow must be maintained, otherwise they may be too rigid (see Fig. 22). Rubber pads usually should be of small area so they can freely squeeze out sideways under load. For a given thickness the hardness of a rubber pad increases disproportionately under compression with increase of area (see Fig. 23.) Rubber must not be used at temperatures of, say, over 120° F. and should be protected from oil. For a discussion of the properties of rubber, and of its design constants see p. 5–27.

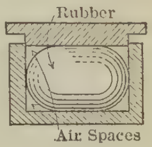

Fig. 22. Rubber Support

**Cork** differs from rubber in that it is directly compressible and space for elastic flow is not needed. See p. 5–25. The stiffness of cork increases directly as its area when used in large pads. Cork pads of comparatively large area thus may be effective in isolation, particularly for higher frequencies in the sound range. Cork has the disadvantage of gradually compressing under load after initial loading, resulting in gradual loss of isolating power for lower frequencies. Despite this fact cork has performed successfully for many years in some installations.

**Gelatin** has elastic properties similar to rubber, but has a lower elastic constant, and thus a lower stiffness. In design, the same considerations enter as for rubber. In its usual form it should not be loaded over 25 lb. per sq. in. It resists oil, but not water. It will fail if heated to 212° F.

**SUSPENSION FREQUENCY CALCULATIONS** for up-and-down frequencies are in all cases made by formula [5], but for rubber, cork and gelatin actual frequency is higher than calculated, due to imperfect elasticity. For some materials, gravity compression $d$ must be greater than required by [5]. For cork, to obtain required suspension frequency, it may be 2 or 3 times as great as for perfectly elastic material like steel.

**REMARKS ON APPLICATIONS.**—General application of elastic suspensions requires considerable knowledge of vibration. Elastic suspensions usually have several modes of vibration. Exciting frequencies, other than the one being isolated, probably will be present, *e.g.*, revolution frequency of a rotating machine operating over a wide range. A suspension must be so designed that all its vibration frequencies avoid all exciting frequencies. An otherwise good elastic suspension may have an objectionable low-frequency quiver. A suspension, flexible in some directions, often must be rigid against belt pull, in which case rubber is better than steel springs. Steel springs sufficiently flexible in one direction may be too flexible in others. Flexible mountings will not successfully operate on a floor that is both light and flexible, *e.g.*, spring suspended machinery on spring supported car bodies, or airplane engines on the relatively light structure. These compound elastic systems with more than one mass and elastic connection, are not readily solved by analysis. Simple cases of suspensions on floors having both elasticity and inertia sometimes can be successfully treated. See Kimball, Vibration Prevention in Engineering, pp. 96–107.

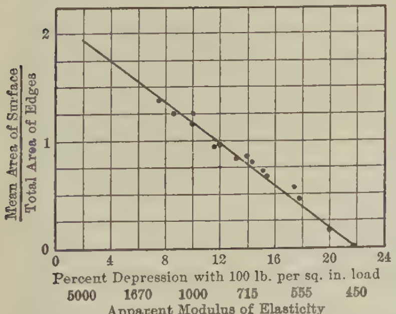

Fig. 23. Apparent Modulus of Compression as a Function of Shape. Tests on ½-in. rubber. Smallest dimension greater than twice the thickness

**FLOOR SUSPENSIONS.**—Some machinery can be isolated by mounting on a comparatively flexible floor frame, elastically supported on the solid floor below. This prevents the transmission of rumbles, grinding noises and hums through the building, to radiate sound from panels, etc. Springs or rubber pad suspensions used at intervals of about 1 ft., depending on the floor load, will perform well, steel being more permanent. The flooring should yield perceptibly, say 0.1 in. under machinery load. A difficulty is the presence of possible side swings and low-frequency quivers, which best are cured by rearranging supports, rather than by calculation. Printing press vibration, for example, has been so isolated. Machinery requiring exact alignment, as an accurate lathe, cannot be placed directly on a flexible floor, but must be set on a rigid, spring-supported platform. Such work is best done by concerns specializing in construction of elastic floorings.

If a cork layer is used instead of a spring-supported flexible floor, low-frequency rumbling noises may be transmitted, if not the higher frequency notes, unless a thick enough layer is used to permit appreciable compression ($^1/_{16}$ to $^1/_8$ in.), under load.

**MOTOR SUSPENSIONS.**—**Single Phase Electric Motors** are subject to torque pulsation of twice the A.C. supply frequency, *i.e.*, 120 cycles per sec. for a 60-cycle source, causing a 120-cycle torsional forced vibration of both stator and rotor about the motor axis. This 120-cycle vibration causes the hum noticed in domestic use of such motors, which a well-designed elastic suspension will completely eliminate. To isolate such 120-cycle vibrations, a suspension of torsion flexibility is required, whose natural frequency $f_0$ about the motor axis is, say, 20 cycles per sec.; since $f = 120$, $f/f_0 = 6$, and from [19], $\epsilon = {}^1/_{35}$, giving fair isolation. This support must have considerable transverse rigidity to resist belt pull, and also to prevent resonating to the speed frequency due to slight mechanical unbalance. Fig. 24 shows an elastic suspension using rubber which is satisfactory.

**Polyphase Electric Motors** with good elastic suspension can be used instead of direct-current motors where noiseless operation is required. While subject to much less vibration than single-phase, no polyphase motor is free from electrical hums which can be transmitted to surrounding structures. The motor may be isolated by mounting on a heavy concrete block supported on a layer of cork, or on cork blocks at isolated points, sufficiently thick to cushion the mass. This construction will be fairly rigid against belt pull. If the motor is placed on the cork footing, without the concrete block, noise probably will be transmitted. Another method is to set the motor on a small area of flexible flooring and avoid low-frequency resonances in the operating range (see Floor Suspensions, above). A third method is to use specially designed elastic bases furnished by the maker. For polyphase motors, the design of such a base is not easy, but correctly designed with rubber pad suspensions, performance is excellent, cost is low, and less space is required than by other methods.

**AUTOMOBILE ENGINE SUSPENSION.**—Flexible supports of comparatively low resonant frequency are being used (1936) on many types of automobile engines with apparent success. Avoidance of suspension resonances is difficult with a wide operating speed range and consequent wide range of exciting frequency. The principal resonant frequency is low and is easily passed through in accelerating the engine. At normal operating speeds, isolation is excellent, and engine vibration is hardly perceptible in the car.

**AIRPLANE VIBRATION.**—A serious difficulty in isolating airplane engine vibration is the relative lightness of the airplane structure, compared with engine weight. A support flexible enough for complete isolation lacks necessary strength. For torsional oscillations a rubber type support is possible, of sufficient torsional flexibility for good isolation and enough transverse rigidity and strength to be safe. This field requires further study.

**ISOLATION FROM VIBRATION.**—The isolation of certain bodies from forced vibrations and waves of outside origin sometimes is necessary. This problem is the reciprocal of that of vibration elimination through tuning (see p. 16-09), and the same principles and formulas apply.

**ISOLATION OF DELICATE APPARATUS** from building tremors requires an idea of the approximate frequencies present, obtained by observing quiver of the surface of a dish of mercury. Building and ground tremors (from vehicles, etc.) contain low-frequency harmonics which can be isolated only by a suspension of frequency of less than one cycle per sec. This follows from transmissibility formula [19], where $f$ is frequency of the building tremor and $f_0$ that of the suspension. Evidently both the up and down oscillating frequency and the sidewise swing of the suspension must be very low. The instrument to be isolated should be hung by long helical springs which extend several inches under the load. See formula [5]. Since a seconds pendulum is about 3 ft. long, suspension springs and wires must be at least several feet long to insure a low enough frequency of sidewise swing.

Several pieces of apparatus may be isolated together on a relatively massive platform hung either from the ceiling or a davit, using springs extending several inches under the load.

Good isolation sometimes can be obtained by placing the apparatus on a heavy metal plate resting on an inflated automobile inner tube. This is not sufficient for very low-frequency disturbances, because to screen from the latter the suspension must yield several inches under load.

All helical springs used in suspensions should be loosely stuffed or wrapped with damping material to prevent local spring resonant oscillations. It is important not to use too much damping as in a spring suspension it *increases* the transmissibility.

**VEHICLE SUSPENSION.**—A successful vehicle suspension should be as flexible or of as low frequency as is consistent with stability. It must have some damping. The lower the frequency the better the isolation from road impulses. Damping is essential in vehicle suspensions, to limit unavoidable resonant bouncing oscillations due to the great range of exciting frequencies produced by various road conditions and speeds.

In railroad cars, the use of built-up leaf springs provides damping by friction between individual leaves. In automobiles, leaf spring friction is not sufficient. So-called shock absorbers are necessary, whose function is to reduce transmissibility at or near suspension resonance points. For other exciting frequencies, transmissibility is slightly increased by such devices.

Automobile suspensions must isolate against more severe vibration excitation than railroad car suspensions. They are of compound character, with one elastic support between wheel and road and another between wheel and car body. Fig. 25 schematically represents such system with damping omitted; $m_1$ represents car body mass; $k_1$, car spring elastic constant; $m_2$, wheel mass; $k_2$, tire elastic constant. Actually the system is more complex, but the scheme of Fig. 25 yields the two principal modes of vibration of ordinary automobile suspensions.

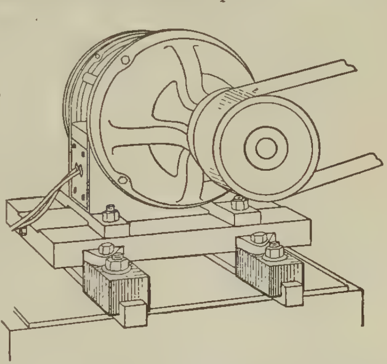

Fig. 24. Elastic Motor Suspension Using Rubber

Due to its compound character, transmissibility is given by an expression which contains both of its two resonant frequencies $f_1$ and $f_2$ as well as exciting frequency $f$ from the road. Where $y_1$ and $y_3$ = amplitudes, this expression is

$$\text{Transmissibility } \epsilon = \frac{y_1}{y_3} = \frac{1}{\{(f^2 - f_1^2)/f_1^2\}\{(f^2 - f_2^2)/f_2^2\}}, \quad . \quad . \quad . \quad [20]$$

The higher resonant frequency $f_1$ is excited by "washboard" roads which causes the wheels to resonate up and down between the road and stops on the vehicle body. This condition arises when $f = f_1$, and without shock absorbers would be excessive. The lower resonance occurs when $f = f_2$, where the whole car body swings up and down in step with long waves in the road. At this frequency shock absorbers again act. This compound system reduces to a simple one, with transmissibility given by [5], when a rigid connection replaces $k_1$. In this case, $f_1$ becomes so large, compared with $f$, that the first factor $(f^2 - f_1^2)/f_1^2$ can be replaced by unity.

This discussion brings out the principal factors in vehicle suspensions. Frequencies $f_1$ and $f_2$ should be as low as possible, so that $\epsilon$ is as small as consistent with stability between resonant points. At the same time, $\epsilon$ is limited at these points by shock absorbers which are not so stiff that $\epsilon$ is appreciably increased between resonant points. For derivation of [20], see Kimball, Vibration Prevention in Engineering, pp. 107–109.

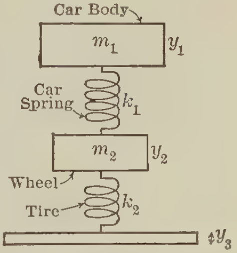

Fig. 25. Diagram of Vehicle Suspension

## 6. VIBRATION DAMPING

Vibration damping is reduction of vibration by friction. Neither avoidance of resonance by tuning nor prevention of transmission by spring suspensions are damping processes. Vibration damping is of maximum effect in curing resonant vibrations where the rate of energy supply exciting vibration is relatively small.

**SLIDING FRICTION DAMPING** exists in built-up leaf springs whose leaves slip against each other, creating friction when the spring oscillates. This friction is important in limiting resonant vibrations of railroad cars on their springs. Sliding friction damping is used in some forms of automobile snubbers.

Torsional oscillations in shafts may be limited by a heavy fly-wheel, attached to the shaft by sliding friction, which slips against oscillations of the shaft. Critical speed vibrations of shafts can be eliminated by spring-supporting bearings in a collar which permits slipping against a friction clamp. Sliding friction dampers often give trouble from variable friction due to variation of pressure of the clamps, to scoring, or to presence of foreign materials like oil.

Sliding friction in the joints is important in limiting vibration of steel structures because of the extremely low internal friction of steel. Turbine wheels with separately-made buckets have far more resistance to vibration than those with buckets integral with the disc.

**IMPACT DAMPING** arises from the impact of loose parts of a structure in an effort to vibrate independently. Such impact has a strong dissipating effect and rapidly damps vibration. A steel gear which otherwise would ring under a hammer blow will sound quite dead if a steel ring is snapped into a slot under the rim on each side. Impact damping is effective in dissipating high-frequency vibrations of small amplitude.

**FLUID DAMPING** differs from sliding friction damping in that in the former, the resisting force rapidly increases with the velocity of motion; in the latter, resisting force is independent of velocity. Dash pots utilizing fluid flow have powerful damping action for large amplitudes, which rapidly falls off with slow motion at small amplitudes.

**SOLID DAMPING.**—All solid materials have more or less internal friction damping resistance to periodic deflection. The most perfect tuning fork loses its vibration amplitude from this cause when all external friction effects, as air resistance, have been removed. Softer elastic materials, as rubber, have considerable internal friction. Steel has so little solid damping that structures built up of steel members owe nearly all of their vibration resistance, as a whole, to sliding and impact friction joints. Individual members and panels, however, may be damped largely through what internal friction exists. Individual members in a steel structure may be very resonant.

Concrete has ten times as much damping as steel, and concrete structures are not particularly resonant. The overall damping in a steel structure does not differ greatly from that of a similar concrete structure, due to dissipation in friction and vibration interference between individual members.

# NOISE

## 1. NOISE IN GENERAL

When vibrations of bodies are transmitted into the air as sound waves of different frequencies, the heterogeneous sound resulting is noise. Noise reduction has (1936) become important in engineering.

**VELOCITY OF SOUND** is a wave phenomenon in the atmosphere. It has constant velocity $V$ of transmission, regardless of its frequency or wave length, of about 1100 ft. per sec.

$$V = \sqrt{1.4\,p\,g/w}, \quad \ldots \ldots \quad [1]$$

where $V$ = velocity, in. per sec.; $p$ = atmospheric pressure, lb. per sq. in.; $g$ = acceleration of gravity, in. per sec. per sec. = 386; $w$ = weight of 1 cu. in. of air. Since $w$ varies as $p$, $V$ is unaltered by pressure change. When temperature increases, however, $w$ alone decreases. Thus while not altered by pressure change, transmission velocity is proportional to the square root of absolute temperature, and varies about 5% in ordinary temperature ranges.

**PERCEPTION OF SOUND.**—The human ear can perceive as tones, noise frequencies from 100 to over 16,000 cycles per sec. In its most sensitive range, 500 to 6000 cycles per sec. the ear is extraordinarily sensitive, the wave amplitude of easily detected sounds being of molecular dimensions. In this range, amplitudes of a fraction of a millimeter are heard as terrific noises. Sounds in this range are easily excited and difficult to eliminate.

**FREQUENCY AND WAVE LENGTH.**—The frequency of a sound is the number of complete waves transmitted per second. High frequencies correspond to short wave lengths and *vice versa*.

$$\text{Wave length} = \lambda = V/f, \quad \ldots \ldots \quad [2]$$

where, if $V$ = in. per sec., and $f$ = cycles per sec., $\lambda$ is in inches. Table 1 compares frequencies and wave lengths in the audible range.

**Table 1.—Sound Frequencies and Wave Lengths**

| Frequency $f$, cycles per sec | 100 | 200 | 500 | 1000 | 2000 | 4000 | 6000 | 10,000 |
|---|---|---|---|---|---|---|---|---|
| Wave length, in | 132 | 66 | 26.4 | 13.2 | 6.6 | 3.3 | 2.2 | 1.3 |

A heterogeneous sound may be made up of wave lengths from this entire range, superimposed on each other, the smaller travelling over the larger. Individual frequencies are called components. In noise work, sound should be considered in terms of its wave length.

**SOUND VELOCITY IN SOLIDS** is much higher than in air. In steel, it is about 17,000 ft. per sec.; in other building materials it is less, but much greater than in air.

**FREQUENCY AND CHARACTER OF SOUND.**—Rumbles and boomings are of long wave length. Ordinary whistling sounds are of intermediate wave length. Tinkling noises and rattling of paper are of higher frequency. Hissing sounds are complex sounds of very high frequency. The whirring of a fan is a very complex noise in which, for small fans, higher frequencies predominate; for large fans and blowers a considerable proportion of low-frequency harmonics are present.

## 2. NOISE MEASUREMENT

**SOUND LEVEL METERS** afford the best means of measuring noise. No short-cut method or cheap type of meter will be satisfactory. The energy associated with sound is very small and the ear itself is such a wonderful detector that high-grade microphones with vacuum tube amplification are essential. The author has obtained excellent results with a General Electric type of meter, which will measure either sound as a whole or, by use of a separate analyzer, measure intensity of the different components present. The meter reads sound level directly in decibels.

**Tuning Forks.**—Much time can be saved in a frequency determination by using a set of tuning forks and noting beats. To determine, for example, whether or not a whistle from a gear is tooth frequency noise, the note frequency is compared with the known frequency of gear tooth impacts.

**Stethoscopes.**—A physician's stethoscope, with a sharp point about 1 in. long fixed to the center of the diaphragm, placed against a vibrating structure is a very sensitive detector of noise transmission which otherwise cannot be heard. By tilting the point in different directions the approximate direction of maximum amplitude can be detected. This instrument can locate node and loop areas on a sounding body of small vibration amplitude.

A steel diaphragm and point near alternating-current electrical apparatus will give a false indication. Disc and point and holder should be of phosphor-bronze or other non-ferrous metals.

**Electro-magnetic Pick-up** based on the phonograph needle principle sometimes is used. Such a device is made for use with the General Electric sound level meter, and very small vibration amplitudes, associated with sound production, can be directly read.

**SOUND LEVEL UNITS. DECIBELS.**—The sound level unit almost universally adopted in commercial work is the *decibel* (db.). Table 2 shows the meaning of the decibel scale in terms of: *a.* Every-day sounds; *b.* Vibrational energy in sound waves; *c.* Amplitude of motion of air particles in a 100- and a 1000-cycle wave; *d.* Rise and fall of pressure in sound waves. The type of noise scale in Table 2 is so constructed that every

**Table 2.—Decibel Scale in Various Units**

| Decibels | Every-day Sounds | Sound Intensity (Threshold = 15 db.) | Half Amplitude of Wave Motion, cm. Cycles 100 | 1000 | Rise and fall of pressure in 1000-cycle wave, dynes per sq. cm. |
|---|---|---|---|---|---|
| 15 | Very low | 1 | ........ | ........ | $10^{-3}$ |
| 25 | Rustle of leaves | 10 | $10^{-7}$ | $10^{-8}$ | .... |
| 35 | Whisper | $10^2$ | ........ | ........ | $10^{-2}$ |
| 45 | Quiet residence | $10^3$ | $10^{-6}$ | $10^{-7}$ | .... |
| 55 | Average residence | $10^4$ | ........ | ........ | $10^{-1}$ |
| 65 | Average business office | $10^5$ | $10^{-5}$ | $10^{-6}$ | .... |
| 75 | Passenger automobile | $10^6$ | ........ | ........ | 1 |
| 85 | 15 to 50 ft | $10^7$ | $10^{-4}$ | $10^{-5}$ | .... |
| 95 | Motor trucks, 15 to 20 ft | $10^8$ | ........ | ........ | 10 |
| 105 | Heavy street traffic in city | $10^9$ | $10^{-3}$ | $10^{-4}$ | .... |
| 115 | Subway express passing through | $10^{10}$ | ........ | ........ | 20 |

Table 3.—Comparison of Noise Values from Several Sources.

| Source 1 | Source 2 | Source 3 | All sources together. Intensity of Source 1 × | Source 1 | Source 2 | Source 3 | All sources together. Intensity of Source 1 × |
|---|---|---|---|---|---|---|---|
| 35 db. | 35 db. | 0 db. | 2 = 38 db. | 40 db. | 40 db. | 0 db. | 2 = about 43 db. |
| 35 " | 35 " | 35 " | 3 = about 40 db. | 40 " | 40 " | 43 " | 4 = " 46 " |
| 35 " | 35 " | 38 " | 4 = " 41 " | | | | |

increase of 10 db. corresponds to 10 times the noise intensity as shown in the third column. Thus a very loud noise of 115 db. is ten billion times as energetic as a very low sound in perfectly quiet surroundings. This scale covers the whole audible sound range in 100 units, and distinguishes noises more nearly as the ear actually does than would a scale based upon energy or pressure units, as given in columns 3 and 6 of Table 2.

For practical purposes it is useful to remember that every 3 db. increase in noise means that the intensity almost exactly doubles. If one noise is 12 db. greater than another, the first noise intensity must be doubled four times, *i.e.*, multiplied by 16, to equal that of the second in intensity, since $^{12}/_3 = 4$. Two noises of equal intensity placed side by side give twice the intensity, or a total noise 3 db. greater than either of them by itself, regardless of their separate noise levels. Examples are shown in Table 3.

**MATHEMATICAL DEFINITION.**—The difference in decibels between two noises of intensities $I_1$ and $I_2$ is defined by the mathematical relation,

$$\text{Difference in db.} = 10 \log_{10} (I_2/I_1); \quad \ldots \ldots \quad [3]$$

$$= 10 \log_{10} (p_1^2/p_2^2) = 20 \log_{10} (p_1/p_2), \quad \ldots \ldots \quad [4]$$

where $p_1$ and $p_2$ are sound pressure amplitudes corresponding to $I_1$ and $I_2$. Expression [4] is multiplied by twice as large a constant as that of [3] because sound intensity is proportional to the square of pressure amplitude of sound waves.

Expressions like [3] and [4] involve only pressure and intensity ratios, and give db. differences. It is thus necessary to define a zero point to fix scale values. Zero decibels loudness level corresponds to sound produced by a 1000-cycle tone with a pressure amplitude of 0.0002 dyne per sq. cm. This sound is just audible in a perfectly quiet room. On such a scale sounds below audibility give negative db. values. Table 3 is derived from these equations, as are the various relations brought out in the discussion of sound level units above.

## 3. NOISE PREVENTION

A noise that cannot be prevented or greatly reduced at the source, by design or by damping, will radiate into the air either directly from the surface of the vibrating body or from parts of the structure to which it is attached. Such noise radiation is *indirect noise*. See Fig. 1, where part of the motor noises radiate directly from the motor and part from panels of the room below, which may resonate to the frequency transmitted.

The following classification is useful when applying a preventive for noise:

| Classification | Method | | |
|---|---|---|---|
| Prevention at Source | Design Changes<br>Damping | | |
| Not readily preventable at source | Direct noise | Screening<br>Absorption<br>Filtration | Higher frequency range, 300 cycles and up. |
| | Indirect noise | Isolation by suspension | Lower frequency range, under 300 cycles. |

A surface vibrating at small amplitude will radiate high frequencies directly into the air much more strongly than low. The latter require much larger vibrating surface area for direct radiation. Hence, in general, direct noises are of higher frequency than indirect; the 300-cycle limit in the classification is an average value.

### Prevention at Source

**DESIGN CHANGES** involve the field of noisy apparatus. This is too large to be considered here, other than to cite a few instances. Remedies must come from studies by manufacturers.

*a.* **Car Wheel Noise.**—Special car wheels with steel rims isolated from the rest of the wheel by rubber are being made (1936) and tested by rubber companies and car wheel manufacturers. Such wheels have greatly reduced track noise of cars.

*b.* **Electric Motors.**—Special studies have produced designs with much lower alternating current electrical hums.

*c.* **Blowers.**—Whistles from blowers in ventilating ducts usually are blade frequency noises, that can be eliminated at the source by design changes.

*d.* **Gear Whistles.**—High-speed gearing can be greatly improved by accurate design to avoid impacts, and by using helical instead of spur gears.

**DAMPING.**—A sounding body, like a gear casing or small blower casing, can be quieted by covering it with a suitable damping material which has the ability to reduce vibrations.

*a.* **Putty Lagging.**—A layer of non-drying putty 1 in. or more thick, covered with varnished cambric or similar material to prevent gradual drying of the putty, sometimes will greatly reduce noise. The putty exerts a powerful damping action, especially on high-frequency whistles and ringing noises, by reducing amplitude of case vibration. Lower frequency rumbling noises are less strongly damped. The higher the frequency, the thinner may be the putty. Suitable non-drying putty can be made by any good chemist. It should have fairly high density and a binder to prevent it falling apart. Before application, the surface should be rubbed with a small amount of putty to improve adhesion.

*b.* **Other Types of Lagging.**—Felt-like materials, when applied as lagging, have far less ability than putty to damp vibrations at the source, though they are sometimes effective as noise reducers. This is due to their high sound absorption coefficients reducing the ability of a surface to radiate noise, and not because they reduce the amplitude of vibration. While these materials are easier to apply, putty is more effective in such applications than any other material used by the author. This is due to its power actually to reduce the surface vibration amplitude.

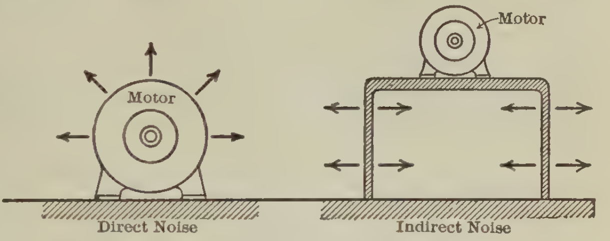

Fig. 1. Direct and Indirect Noise

Resinous and tar-like materials when applied as lagging offer great friction to slow vibratory deflections of large amplitude. They are of relatively little use in damping high frequency vibrations of small amplitude, aside from the increase in surface mass that they produce. These vibrations are so rapid that flow, with its attendant friction, does not occur. The relative vibration absorption ability of different laggings is tested by coating the material on a steel diaphragm welded to a short pipe to support its edges. If the diaphragm be resonated by an electromagnet of variable frequency it emits a loud sound unless the lagging is an effective damper. Impacting with a hammer is a good test if an electro-magnet is not available.

The correct use of acoustic felts is the absorption of sound *after* sound waves are on the air. In this application putty is of small value, compared to felt and similar materials.

## Screening and Transmission

**SCREENING OF SOUND.**—Noise is screened either to confine it in a given space, or to maintain a given space noise-free. In either case the principle used is the same, *i.e.*, to construct screens or walls highly resistant to noise transmission. The problem thus is one of the noise transmission.

**PROCESS OF TRANSMISSION.**—Sound is transmitted through a wall by air pressure oscillations produced on its farther side by leakage, or more commonly, by oscillations produced by vibrations of the wall itself. This latter phenomenon usually occurs regardless of the presence of the former. Porous, felt-like materials transmit largely through leakage of wave oscillations.

Ordinary wood and plaster walls transmit by motion of the wall itself, or by vibration of portions of the wall. This is evident from Table 1 showing wave lengths of various sound frequencies. These are much in excess of the thickness of most walls, except those of high frequency, which are not readily transmitted. Sound waves of a given frequency in wall materials must be several times longer than in air, in proportion to the higher sound transmission velocity of these materials. Only the highest frequencies in the audible range can exist as complete individual waves during transmission through ordinary wall.

**Leakage.**—Small holes or cracks in a wall, otherwise highly resistant to noise transmission, will pass a surprising amount of sound, unless the crack is deep. Considerable damping action then is introduced by air friction on the crack sides. A sound-proof room or box must have tight fitting doors.

**MEASUREMENT OF SOUND TRANSMISSION** involves resonant effects depending upon mass, elastic characteristics and structure of the partition as determined by its dimensions, and reflection effects influencing the observations of the transmitted sound.

In engineering, a sound meter of the type described on p. 16–19 will indicate the intimate effect of the acoustics of the immediate surroundings. For example, the noise level in an ordinary room may fluctuate widely from place to place because of systems of standing sound waves which may be present. The ear will detect nodes and loops when the head is swinging back and forth, if one or two fairly strong tones are present in a room.

**FACTORS INFLUENCING TRANSMISSION.**—Noise is transmitted primarily by vibratory motion of a wall as a whole. Important factors in transmission prevention are mass per unit area and stiffness.

Stiffness is a trouble rather than an aid in the transmission resistance of walls, unless the wall is thick, of relatively small area, and unable to resonate to any objectionable noise harmonics. A small rigid metal case may resist noise transmission largely due to rigidity rather than to mass per unit area.

Ordinary walls have various flexural resonant frequencies well below some objectionable noise harmonics. Stiffness can never aid such cases. It slightly increases wall vibration amplitude, but this effect is negligible for relatively high frequencies.

A third factor whose influence is important is wall structure. A double wall, with air space unbridged by rigid members, may resist noise transmission far more than a single wall of the *same total weight* per sq. ft.

**DESIGN OF WALLS OF LOW TRANSMISSIBILITY.**—A double wall is more desirable than a single wall, being cheaper and less massive for the same transmission loss. A comparatively rigid skeleton of ordinary 2 × 4-in. studding should be used, with inner and outer walls hung from it by spring connections. These walls, of celotex or similar material, should weigh from 1 to 5 lb. per sq. ft. A thin layer of plaster-like reinforcement is helpful. Besides adding mass, it decreases porosity, which is an advantage. The celotex may be reinforced by thin sheet iron. Sheet iron must not be used without celotex, as it is subject to resonances.

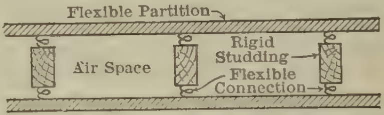

Fig. 2. Wall Construction of Low Transmissibility

Spring connectors eliminate the bridging effect of studding, which results when the walls are directly nailed to it. Steel spring connectors should be set on felt pads to reduce possible high-frequency vibration transmission through the springs. Such a wall has an air space of about 5 in., which is fair spacing. Air spacings of the order of 1 in. are much less effective, while more than 6 in. spacing usually is unnecessary. See Fig. 2. If sound resistance required is not high, celotex may be nailed directly to studding on both sides, but the advantage of the air space, which is large, is then much reduced.

A single wall should be of brick or masonry to have enough mass to be effective. A heavy masonry wall has high transmission resistance, but is expensive and cumbersome. This type of wall is not particularly susceptible to resonances, its transmission resistance being due almost entirely to its mass.

Double walls of comparatively small mass, as recommended above, should have some damping, such as contained in a material like celotex, to avoid resonances.

**TRANSMISSION LOSS.**—The aim of a sound-proof wall or partition is to have sufficient transmission loss to be effective. This increases as the frequency rises. Table 4 gives an average transmission loss over the audible frequency range. It is about the same order as that for a pure 500-cycle sound. Transmission loss is measured by the observed drop in sound intensity in decibels produced by the wall, and is independent of the intensity of sound being screened. A wall causing a drop in noise level from 64 to 34 db. will also cause a drop from 54 to 24 db., *i.e.*, transmission loss is 30 db. The author has no figures at hand for a double wall of the type first recommended, but the transmission loss is high, from 40 to 60 db.

**PRECAUTIONS.**—Several precautions are necessary in the design of transmission resisting walls and screens, after the design of the wall itself has been decided.

**Transmission from Footing.**—Studding should be set on a layer of yielding material to prevent transmission to wall from ground or other support. A layer of felt under the sill is good, but by itself becomes rather hard. By the principles of vibration isolation (see p. 16–14), a gravity elastic deflection of $^1/_8$ in. or more is desirable. Cork is rather hard, but if sufficiently thick should prevent transmission of higher frequencies.

**Transmission through Pipes and Ducts.**—Metallic pipes are effective transmitters

Table 4.—Transmission Loss Produced by Various Partitions.*

| No. | Description | Transmission Loss, db. | Lb. per sq. ft. |
|---|---|---|---|
| 1. | Steel, 1/4 in. thick | 30.0 | .... |
| 2. | Solid oak, 1 3/4 in. thick | 20.9 | .... |
| 3. | Plate glass, single pane, 1/4 in. thick | 22.8 | .... |
| 4. | Plate glass, 2 panes, 3/16 in. thick | 19.7 | .... |
| 5. | Hair felt, 3 in. thick | 11.8 | .... |
| 6. | 3 layers 1-in. felt alternated with 4 layers building paper | 27.9 | .... |
| 7. | 2-in. gypsum tile, unplastered | 20.2 | 10.4 |
| 8. | 3-in. gypsum tile, unplastered | 23.7 | 14.2 |
| 9. | 4-in. clay tile, unplastered | 28.8 | 17.0 |
| 10. | 4-in. clay tile, 1/2-in. plaster | 30.8 | 22.0 |
| 11. | 8-in. brick wall, 1-in. plaster | 46.1 | 88.0 |
| 12. | Double 2-in. solid gypsum tile, unplastered unbridged, 4-in. separation | 51.8 | 20.4 |
| 13. | Same as 12, but bridged at top and bottom | 46.9 | 20.4 |
| 14. | Same as 12, inner faces lined with 1-in. felt | 57.3 | 22.3 |
| 15. | Staggered 2 × 4 in. wood studs, metal lath. 1/2-in. gypsum plaster | 39.1 | 19.8 |
| 16. | Same as 15, with 1/2-in. celotex instead of metal lath | 36.6 | 13.0 |

* Taken from work done under direction of Dr. Paul Sabine at Riverbank Acoustical Laboratory. See P. E. Sabine, Sound Transmission through Walls, *Jour.* Acoustical Soc., June, 1930, pp. 181–207. Also Sabine, Acoustics and Architecture, chap. xii. (McGraw-Hill.)

of sound. Two or three pipes in a well-designed sound screen may greatly reduce its effectiveness. Transmission along a metallic pipe can be greatly reduced by rubber joints to prevent metallic contact of pipe sections. For air ducts, heavy canvas connections are effective. Direct transmission of sound through ventilating ducts may be considerable. See p. 16–24.

**Edges of Double Walls.**—The sound-insulating properties of elastically suspended wall partitions used with double walls requires edges to be free from rigid contacts with the frame, at the same time avoiding cracks through which sound can pass. Cracks can be stuffed with felt or similar material.

## 4. ABSORPTION OF SOUND

If directly radiated noise, as the noise in a business office or in a factory, cannot be screened, a decided reduction in the noise level can be made by means of sound absorbing materials. Sound absorption takes place during wave reflection. It is measured by the fraction of the incident energy which disappears in a single reflection. An open window space reflects practically no sound and represents a maximum obtainable reduction.

Table 5, by Watson, gives sound absorption coefficients of various materials based on unity as absorption of an open window. See F. R. Watson, Absorption of Sound by Materials, Univ. of Ill. *Bull.* 172, 1927. Also P. E. Sabine, Acoustics and Architecture. Felt-like materials have high sound absorbing power, as have certain porous materials. A good absorbent covering has a smooth surface layer of oilcloth or thin metal perforated with many holes, under which is a porous material. Such covering gathers less dust than a felt-like surface and is just as effective.

Table 5.—Sound Absorption Coefficients of Different Materials at 512 Cycles per sec. Pitch

| Description | Coefficient | Description | Coefficient |
|---|---|---|---|
| Open window | 1.0 | Carpet | 0.20 |
| Brick wall | 0.032 | Curtains, heavy folds | 0.40–0.75 |
| Brick wall, painted | 0.017 | Hairfelt, 1 in. thick | 0.59 |
| Wood, planed | 0.06 | Rock wool | 0.57 |
| Wood, varnished | 0.03 | Balsam wool, 1 in. thick | 0.61 |
| Plaster on lath | 0.034 | Good acousti-celotex, 441 small holes per sq. ft | 0.70 |
| Glass (single thickness) | 0.027 | | |
| Marble | 0.01 | | |

Sound absorption and transmission resistance are entirely different processes. A good sound absorber, as felt, is a poor transmission preventive. Such a material may be effectively used, however, as a lining of an enclosed space to further reduce the final noise level obtained by screening. If no sound resisting walls were used with the absorbing layer, however, the noise level would be very much raised.

**CALCULATION OF NOISE REDUCTION THROUGH ABSORPTION.**—When the noise level in a room and the sound absorption coefficients of its walls (Table 5) are known, the possible reduction in noise level through the use of more absorbent materials on the walls can be approximately calculated. From [4],

$$\text{db.} = 10 \log_{10} (a_2/a_1) \quad \ldots\ldots\ldots \quad [5]$$

To find $a_1$, multiply wall area of each part of room by its absorption coefficient. If $S$ = total area, and if the coefficient of $^1/_6\, S = 0.03$, of $^1/_3\, S = 0.01$, and of $^1/_2\, S = 0.02$, then $a_1 = \{(S/6) \times 0.03\} + \{(S/3) \times 0.01\} + \{(S/2) \times 0.02\} = (S/6) \times 0.11$. Assume that the part of the surface whose coefficient is 0.02 to be covered with an absorbent with a coefficient of 0.50. Then

$$a_2 = \{(S/6) \times 0.03\} + \{(S/3) \times 0.01\} + \{(S/2) \times 0.50\} = (S/6) \times 1.55,$$

and $a_2/a_1 = 155/11 = 14.1$. From [5], db. $= 10 \log 14.1 = 10 \times 1.492 = 11.49$. If all the walls and the floor were covered with such a material, $a_2 = (S/6) \times 3.00$; $a_2/a_1 = 300/11 = 29.2$, and db. $= 10 \log 29.2 = 10 \times 1.4654 = 14.65$. Thus covering half the whole area would reduce the noise level by 11.49 db., but covering the whole area would reduce it only a little over 3 db. more.

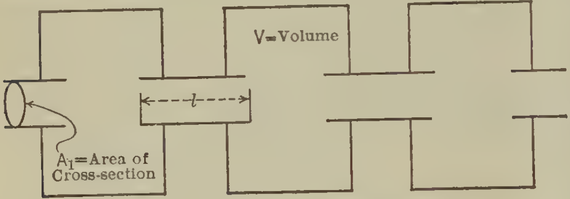

FIG. 3. Low-pass Acoustic Filter

The conclusion is that in reducing noise level by sound absorbing materials on the walls, the greatest reduction is effected by the first part of the walls covered. After this, less and less improvement is obtained from a given area of absorption covering. It usually is sufficient to treat only part of the wall area of a noisy room. Sound absorbing materials should be so used in interiors that they may reduce the noise by many back and forth reflections.

Table 5 is based upon absorption coefficients at 512 cycles per sec. Higher frequencies are absorbed more and lower frequencies less. The use of the correct amount of absorption on the interior walls of lecture and music halls is an important field of acoustic engineering, known as architectural acoustics. See P. E. Sabine, Acoustics and Architecture, chap. viii.

**NOISE ABSORPTION IN DUCTS.**—Noise in ventilating ducts can be greatly reduced by linings of acoustic absorbent materials. This is particularly true of the higher-frequency rushing noises and hisses. Hums and whistles are not so easily eliminated, and require other means of treatment. See Acoustic Filters, below.

## 5. FILTRATION OF SOUND

**ACOUSTIC FILTERS IN GENERAL.**—When direct noise, containing definite notes or harmonics, is transmitted along ducts or through openings, it often is possible to completely eliminate objectionable harmonics by an acoustic filter, which obstructs but little air flow or ventilation. Sound filters are of two classes: 1. Low-pass filters which transmit low frequencies, but filter out the higher ones; 2. High-pass filters which do the opposite. A low-pass filter prevents transmission of the relatively high whistle often present in a ventilating duct. Low frequencies, predominant in explosive discharges, are filtered out by a high-pass filter, as an automobile muffler or Maxim silencer.

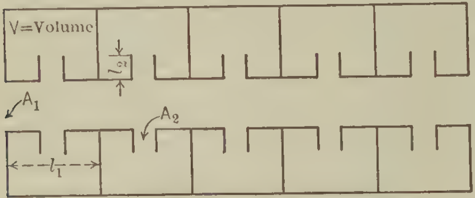

FIG. 4. Type 2, Low-pass Acoustic Filter

Space is the usual limitation in filter applications. This restricts for low-pass filters less than high-pass. Low-pass filters return sound energy to the source, where it dissipates itself through reflections, etc. High-pass filters must themselves dissipate the sound, this being an important reason for their comparative bulk. The individual stages of a filter must be considerably shorter than the wave length of sound being filtered, each stage producing a definite amount of attenuation, as illustrated by the specific types of design which follow.

**LOW-PASS FILTERS** may be divided into two classes of design. Fig. 3 shows the first, and Fig. 4 the second. In designing a filter, the lower limit of frequency $f_0$ is determined, below which it will transmit, and above which the filtering action begins.

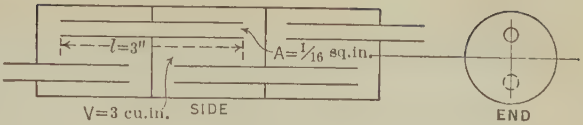

Fig. 5. Special Filter Design

For Type 1 of Fig. 3, $$f_0 = 4200\sqrt{A_1/(lV)} \qquad [6]$$
where $A_1$ = area of cross-section, sq. in.; $l$ = length, in., $V$ = volume, cu. in. and where the symbols refer to Fig. 3.

For Type 2, Fig. 4, $$f_0 = 4200\sqrt{\frac{1}{V\{(l_1/A_1)+4(l_2/nA_2)\}}} \qquad [7]$$
which in most cases can be replaced by the more approximate formula
$$f_0 = 2100\sqrt{nA_2/l_2V} \qquad [8]$$
where the symbols refer to Fig. 4, and $n$ = number of passages per stage of sectional area $A_2$. If $l_2$ is very small, such that $A_2$ is a simple orifice, the ratio $A_2/l_2$, is replaced by $D$, the diameter of the orifice. If there are a number of passages or orifices $n$ in each stage, $A_2/l_2$, or $D$, must be multiplied by that number.

Example of Design of Type 1 Filter.—A whistle of about 400 cycles frequency is emitted from a tube of $1/16$ sq. in. cross-sectional area. A Type 1 filter, Fig. 3, should eliminate this sound. $A_1 = 1/16$ sq. in.; $l$ = 3 in.; $V$ = 3 cu. in. Fig. 5 is a section of the filter in three stages, the two end tubes being shortened. From [6], $f_0 = 4200\sqrt{1/16 \times 1/3 \times 1/3} = 350$ cycles. The lower frequency limit of this filter being 350 cycles, the 400-cycle frequency should be eliminated. The wave length of this sound is $(1100/400) \times 12 = 33$ in., which is greater than the filter stage length. For higher frequencies, where the wave length is below 6 in., the filtering action will fall off.

Example of Design of Type 2 Filter.—Apply this type of design to the previous problem. Type 2 filters are more selective than Type 1, as filtering action is efficient only for frequencies near and just above the lower limiting frequency $f_0$. Fig. 6 is a design which should be satisfactory. Applying approximate formula [8] and design data from Fig. 6, $f_0 = 2100\sqrt{1/4 \times 2 \times 1/16} = 372$ cycles. The more exact formula [7] will give a slightly lower frequency, but sufficiently near 400-cycles to have a strong attenuating action on it. This design also consists of stages which are short compared with the wave length of the sound to be filtered. The filtering action of Type 1 low-pass filter covers a broader range of frequency than Type 2 and is very efficient. Type 2, however, can sometimes be designed to occupy considerably less space than Type 1. The preferred type depends on conditions to be met.

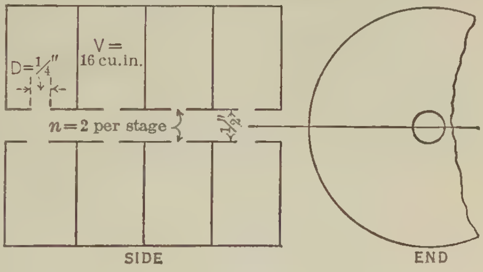

Fig. 6. Special Filter Design

**HIGH-PASS FILTERS** are not so efficient in performance as low-pass filters, and are, as a rule, more bulky. Fig. 7 is a typical high-pass filter of simple design. The limiting frequency, above which such a filter ceases to perform, is
$$f_0 = 2100\sqrt{nA_2/A_1 l_1 l_2} \qquad [9]$$
The symbols are shown in Fig. 7, and, as before, $A_2/l_2 = D$ = hole diameter when $l_2$ is small, and $n$ = number of holes of area $A_2$ per stage.

This type of filter functions through successive side leakage of pressure waves as they pass through the tube. When the wave escapes from the tube end, its pressure amplitude and its intensity are greatly reduced. An appreciable amount of sound, however, escapes through the side holes. Good high-pass filters require an outer shell of considerably larger diameter than the inner tube, the interspace being stuffed with a damping material as metal wool or shavings. Steel wool will rust in gas engine exhaust mufflers.

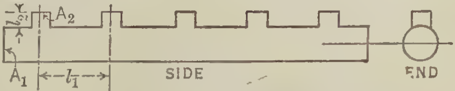

Fig. 7.—High-pass Filter

Fig. 8 is a cross-section of an efficient muffler which has considerably less back pressure than the baffle-type automobile muffler. For high attenuation, many small holes are better than the few large ones in Fig. 6. The use of formula [9] is not necessary for explosion mufflers, as these filters always attenuate low frequency impulse waves. This formula will show that the limit $f_0$, above which attenuation ceases, is well above these low frequencies, being seldom below 100 cycles per sec.

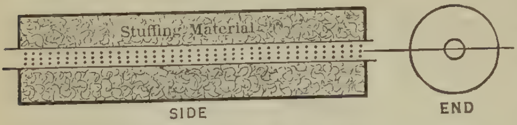

FIG. 8. Explosion Muffler

**PERFORMANCE.**—An ideal sound filter produces a certain percentage drop in sound intensity per stage for every frequency within its range of attenuation. Thus, a 6-stage low-pass filter may attenuate a 300-cycle tone by 4 db. per stage, or 24 db. in all. A sharply tuned Type 2 low-pass filter will attenuate much more. Attenuation in db. per stage is independent of the initial sound intensity.

Performance of a low-pass filter sometimes is disappointing. Tube resonance effects must be avoided. A tube of length equal to a multiple of one-half the wave length of sound of a given frequency will resonate to that frequency. An otherwise well-designed filter may not perform well if such effects enter; placing it in different positions in the duct usually will eliminate them. High-pass filters, as mufflers, are less subject to this trouble. A fairly good knowledge of the elementary principles of sound is desirable in making sound filter applications. For a discussion of sound filtration, see Stewart and Lindsay, Acoustics, chap. vii (D. Van Nostrand Co., N. Y.).

## 6. INDIRECT NOISE

Indirect noise is the result of transmission through a structure of sound vibration from an exciting source which may be quite remote. An ordinary structure has ability to transmit vibration waves a long distance almost perfectly noiselessly to some point. For example, a panel with the same natural frequency as the wave, may resonate with surprising strength. The source of vibration sometimes is hard to find. The treatment of indirect noise is to isolate the source by elastic suspension. Vibration isolation is discussed on p. 16–14; the same methods apply to cases of noise isolation.

# STRUCTURES AND BUILDINGS

## STRESSES IN FRAMED STRUCTURES

Framed structures in general consist of one or more triangles, for the reason that the triangle is the one polygonal form whose shape cannot be changed without distorting one of its sides. Problems in stresses of simple framed structures generally may be solved either by the application of the triangle, parallelogram, or polygon of forces, by the principle of the lever, or by the method of moments.

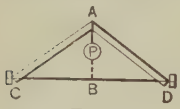

FIG. 1

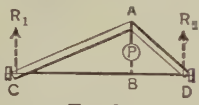

FIG. 2

**MAXIMUM THRUST OR TENSION IN TRUSSES** is at the center of the horizontal chords. It is equal to $WL/8D$, where $W$ = total load supported by truss, including weight of truss; $L$ = length and $D$ = depth of truss.

**TWO DIAGONAL BRACES AND A TIE ROD.**—If the braces are of equal length (Fig. 1), and sustain a single load $P$, compressive stress $S$ in each brace is as follows:

$$S_{AD} = {}^1/_2 P \times (AD/AB); \quad S_{AC} = {}^1/_2 P \times (AC/AB).$$

Each abutment $C$ and $D$ supports one-half the load $P$.

If the braces are of unequal length (Fig. 2),

$$S_{AC} = R_1 \times (AC/AB); \quad S_{AD} = R_2 \times (AD/AB),$$

where $R_1$ and $R_2$ are the reactions on the abutments $C$ and $D$ respectively. Let load $P$ be applied at point $B$ on $CD$. Then

$$R_1 = P \times (BD/CD); \quad R_2 = P \times (BC/CD).$$

Stress in tie $CD$ is

$$S_{CD} = R_1 \times (CB/AB) = R_2 \times (BD/AB).$$

If $\quad CB = BD, R_1 = R_2 \quad$ and $\quad S_{CD} = {}^1/_2 P \times {}^1/_2 (CD/AB).$

If the braces support a uniform load, as in a pair of rafters, the stresses are equivalent to those set up by one-half the load applied at the center. The horizontal thrust of the braces against each other at the apex equals the tensile stress in the tie $CD$.

**KING-POST TRUSS.**—See Fig. 3. Braces $AC$ and $AD$ are in compression; strut $AB$ and tie $CD$ are in tension. A uniform load $P$ may be considered as a concentrated load ${}^1/_2 P$ at the center. Then the stresses in the several members are:

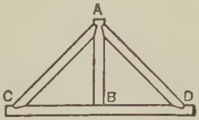

FIG. 3. King Post Truss

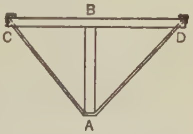

FIG. 4. Inverted King Post Truss

$$S_{AC} = S_{AD} = {}^1/_4 P \times (AD/AB) = {}^1/_4 P \times (AC/AB);$$
$$S_{AB} = {}^1/_2 P; \quad S_{CD} = {}^1/_4 P \times (BD/AB).$$

Horizontal thrust of brace $AD$ at $D = S_{CD}$.

If the truss is inverted, as in Fig. 4, the stress is compression in the strut $AB$ and tension in members $AC$ and $AD$.

**QUEEN-POST TRUSS.**—Members $AB$, $BC$, and $CD$, Fig. 5, are in compression; $AD$, $BE$ and $CF$ are in tension. If the queen-posts $BE$ and $CF$ divide $AD$ into three equal parts, a uniform load may be considered as divided also in three equal parts, two of which are concentrated at $E$ and $F$, the remaining part being divided between the two abutments at $A$ and $D$.

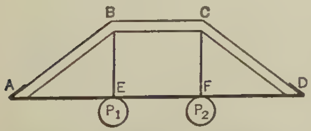

FIG. 5. Queen Post Truss

Only the loads $P_1$ and $P_2$, concentrated at $E$ and $F$ respectively, are considered as affecting the members of the truss. Stresses are as follows:

$$S_{BE} = P_1;\quad S_{CF} = P_2;\quad S_{CD} = S_{AB} = P_1 \times (CD/CF) = P_2 \times (AB/BE);$$
$$S_{AE} = S_{EF} = S_{FD} = P_1 \times (FD/CF) = P_2 \times (AE/BE).$$

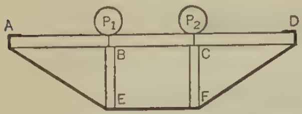

FIG. 6. Inverted Queen Post Truss

Thrust on $BC$ = tension in $EF$. To resist heavy unequal loads, diagonal braces should be provided from $E$ to $C$ and from $B$ to $F$.

If the truss is inverted, as in Fig. 6, $AB$, $BC$, $CD$, $BE$ and $CF$ are in compression. $AE$, $EF$ and $FD$ are in tension.

**BURR TRUSS OF FIVE PANELS** (Fig. 7).—If the panels are of equal length, $^1/_5$ of the load may be considered as being concentrated at each panel point, and $^1/_5$ divided equally between the two abutments. To determine stress in $AB$ and $CD$, consider the truss as a queen-post truss, with loads $P_1$ and $P_2$ concentrated at $E$, and loads $P_3$ and $P_4$ concentrated at $F$. To determine stress in $GE$ and $HF$, consider the portion of the truss between $E$ and $F$ as a smaller queen-post truss with loads $P_2$, $P_3$ at $K$ and $L$ respectively. The stresses are

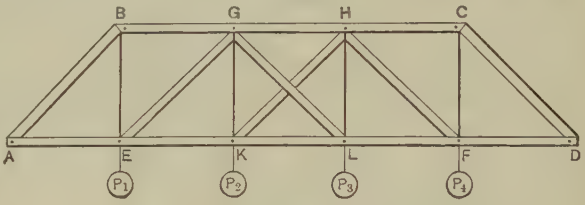

FIG. 7. Burr Truss

$S_{AB} = S_{CD} = (P_1 + P_2) \times (AB/BE) = (P_3 + P_4) \times (CD/CP)$ . [compression]
$S_{GE} = S_{HF} = P_2 \times (GE/GK) = P_3 \times (HF/HL)$ . . . . . . . [compression]
$S_{BE} = S_{CF} = P_1 + P_2 = P_3 + P_4$ . . . . . . . . . . [tension]
$S_{GK} = S_{HL} = P_2 = P_3$ . . . . . . . . . . . . [tension]
$S_{BG} = S_{CH} = (P_1 + P_2) \times (AE/BE) = (P_3 + P_4) \times (FD/FC)$ . . [compression]
$S_{GH} = (P_1 + P_2 + P_3) \times (AE/BE)$ . . . . . . . . . . [compression]
$S_{AE} = S_{FD} = (P_1 + P_2) \times (AE/BE) = (P_3 + P_4) \times (FD/FC)$ . [tension]
$S_{EK} = S_{KL} = S_{LF} = (P_1 + P_2 + P_3) \times (AE/BE)$ . . . . . . [tension]

Stress is received by $GL$ and $HK$ only when the truss is unequally loaded.

**PRATT OR WHIPPLE TRUSS** (Fig. 8).—In this truss, diagonals are ties and verticals are struts. The general formula for stress in the verticals with a uniformly distributed static load is

$$S_v = [\{(n - x) + (n - x)^2 - (x - 1) + (x - 1)^2\}P]/2n,$$

and for a moving load

$$S_{vr} = \frac{\{(n - x) + (n - x)^2 - (x - 1) + (x - 1)^2\}P}{2n} + \frac{r(x - 1) + (x - 1)^2}{2n}$$

where $n$ = number of panels in truss; $x$ = number of any vertical, considered from the nearest end, and counting the end as 1; $r$ = moving load for each panel; $P$ = total load for each panel.

Stress in principal diagonals ($AJ$, $GN$, etc.) is

$$S_D = S_v \sec \theta,$$

where $\theta$ = angle which the diagonal makes with the vertical, *e.g.* angle $AJB$ or angle $HBJ$.

Stress $S_C$ in counterbraces ($BH$, $CJ$, $FO$, etc.) depends on the position of the brace. If the load is uniform, $S_C = \theta$ in the first panel.

In the second panel, $S_C = P \sec \theta \times (1/n)$.

In the third panel, $S_C = P \sec \theta \times \{(1 + 2)/n\}$.

In the fourth panel, $S_C = P \sec \theta \times \{(1 + 2 + 3)/n\}$, etc.

**Calculation by Distribution of Stress.**—Assume a truss of six panels, uniformly loaded with a total load $P$. The portion of the load applied at each panel point may be considered as $^1/_6 P$. The loads transmitted to the abutments from each panel are as follows:

| | Load $P_1$ | $P_2$ | $P_3$ | $P_4$ | $P_5$ |
|---|---|---|---|---|---|
| To abutment $H$.................... | $^5/_6 P_1$ | $^4/_6 P_2$ | $^3/_6 P_3$ | $^2/_6 P_4$ | $^1/_6 P_5$ |
| To abutment $O$.................... | $^1/_6 P_1$ | $^2/_6 P_2$ | $^3/_6 P_3$ | $^4/_6 P_4$ | $^5/_6 P_5$ |

Each of the above loads is transmitted through each strut and tie between its point of application and the abutment. Thus $^5/_6\,P_1$ is transmitted through members $JA$ and $AH$ to abutment $H$ and $^1/_6\,P_1$ is transmitted through members $JC$, $CK$, $KD$, $DL$, $LE$,

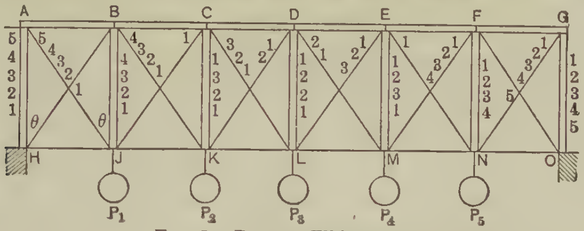

FIG. 8. Pratt or Whipple Truss

etc., to abutment $O$. Similarly, $^4/_6\,P_2$ is transmitted through $KB$, $BJ$, $JA$, and $AH$ to abutment $H$, and $^2/_6\,P_2$ is transmitted through $KD$, $DL$, $LE$, etc., to abutment $O$. As each load is thus analyzed, the numerator of the fraction of load transmitted may be written alongside the member affected as in Fig. 8 or tabulated as follows:

Diagonals in Tension

| | AJ | BH | BK | CJ | CL | DK | DM | EL | EN | FM | FO | GN |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| $P_1$........ | 5 | ..... | ...... | 1 | ...... | 1 | ...... | 1 | ...... | 1 | ...... | 1 |
| $P_2$........ | 4 | ..... | 4 | ..... | ...... | 2 | ...... | 2 | ...... | 2 | ...... | 2 |
| $P_3$........ | 3 | ..... | 3 | ..... | 3 | ...... | ...... | 3 | ...... | 3 | ...... | 3 |
| $P_4$........ | 2 | ..... | 2 | ..... | 2 | ...... | 2 | ...... | ...... | 4 | ...... | 4 |
| $P_5$........ | 1 | ..... | 1 | ..... | 1 | ...... | 1 | ...... | 1 | ...... | ...... | 5 |
| Total $T_t$ .. | 15 | 0 | 10 | 1 | 6 | 3 | 3 | 6 | 1 | 10 | 0 | 15 |

Struts in Compression

| | AH | BJ | CK | DL | EM | FN | GO |
|---|---|---|---|---|---|---|---|
| $P_1$........... | 5 | .......... | 1 | 1 | 1 | 1 | 1 |
| $P_2$........... | 4 | 4 | .......... | 2 | 2 | 2 | 2 |
| $P_3$........... | 3 | 3 | 3 | .......... | 3 | 3 | 3 |
| $P_4$........... | 2 | 2 | 2 | 2 | .......... | 4 | 4 |
| $P_5$........... | 1 | 1 | 1 | 1 | 1 | .......... | 5 |
| Total, $T_c$..... | 15 | 10 | 7 | 6 | 7 | 10 | 15 |

$$\text{Tension in the diagonals} = T_t \sec\theta \times {}^1/_6\,P.$$

$$\text{Compression in struts} = T_c \times {}^1/_6\,P.$$

If diagonal struts are used at $HB$ and $FO$, instead of the struts $AH$, $GO$ and the diagonals $AJ$, $GN$, $^5/_6\,P$ will be carried through $FN$ and $NO$. Stress in $BH$ and $FO$ will equal $^{15}/_6\,P\sec\theta$.

Stresses in upper chords are compression, and in lower chords are tension. They increase from the ends to the center. The thrust in each member as $AB$, $BC$, etc., is the horizontal component of the tension in the diagonal of the panel, plus the thrust on the members between it and the end of the truss. Thus,

$$\text{Thrust in } AB \text{ and } FG = {}^{15}/_6\,P \times \tan\theta.$$

$$\text{Thrust in } BC \text{ and } EF = {}^{15}/_6\,P \times \tan\theta + {}^{10}/_6\,P\tan\theta.$$

$$\text{Thrust in } CD \text{ and } DE = {}^{15}/_6\,P\tan\theta + {}^{10}/_6\,P\tan\theta + {}^{6}/_6\,P\tan\theta.$$

The tension in the lower chord of each panel is the same as the thrust in the upper chord of the panel. See Method of Moments below.

If loads $P_1$, $P_2$, $P_3$, etc., are unequal, the value of each must be taken into account in distributing stress. Thus tension in $AJ$, instead of being $^{15}/_6\,P\sec\theta$, would be

$$\sec\theta\,({}^5/_6\,P_1 + {}^4/_6\,P_2 + {}^3/_6\,P_3 + {}^2/_6\,P_4 + {}^1/_6\,P_5).$$

Each panel load should include its fraction of the weight of the truss.

**Method of Moments.**—Let the truss be uniformly loaded with a total load $= W$. Weight supported at each end, or reaction of the abutment $= W/2$. Length of the truss $= L$. Weight on a unit of length $= W/L$. Horizontal distance from nearest abutment to any point (say $M$, Fig. 8) in the chord where stress is to be determined $= x$. Horizontal stress at that point (tension on the lower chord, compression in the upper) $= H$. Depth of the truss $= D$. The difference of the moment about the point $M$ of the reaction of the abutment, and of the moment of the load between $M$ and the abutment, is equated to the moment of resistance or stress in the horizontal chord, considered with reference to the point in the opposite chord about which the truss would turn if the first chord were severed at $M$.

$$\text{Moment of reaction of abutment} = (W/2) \times x.$$

$$\text{Moment of load from abutment to } M = (W/Lx) \times (x/2) = Wx^2/2\,L.$$

$$\text{Moment of stress in chord} = HD = (Wx/2) - (Wx^2/2\,L),$$

whence

$$H = (W/2\,D)\{x - (x^2/L)\}.$$

**THE HOWE TRUSS** (Fig. 9).—In the Howe truss the diagonals are struts, and the verticals are ties. The calculation of stress may be made in the same method as described for the Pratt truss.

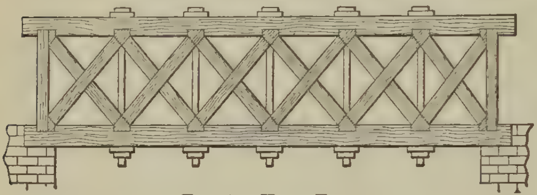

FIG. 9. Howe Truss

**THE WARREN GIRDER** (Fig. 10) has no vertical struts, and the diagonals may transmit either tension or compression. Stresses in the diagonals may be calculated by the method of distribution of stresses as in the case of the rectangular truss.

The loads $P_1$, $P_2$, $P_3$, etc., are respectively $^1/_{10}$, $^3/_{10}$, $^5/_{10}$, etc., of the length of the span from $a$, and the loads transmitted to the abutments from each panel are as follows:

| | Load $P_1$ | Load $P_2$ | Load $P_3$ | Load $P_4$ | Load $P_5$ |
|---|---|---|---|---|---|
| To abutment $a$............... | $0.9\,P_1$ | $0.7\,P_2$ | $0.5\,P_3$ | $0.3\,P_4$ | $0.1\,P_5$ |
| To abutment $g$............... | $0.1\,P_1$ | $0.3\,P_2$ | $0.5\,P_3$ | $0.7\,P_4$ | $0.9\,P_5$ |

These quantities can be written alongside the members affected by the transmission of the several loads, tension values being written to the left and compression values to the right as shown in Fig. 10, or they can be tabulated as below.

| | $a1$ | $b1$ | $b2$ | $c2$ | $c3$ | $d3$ | $d4$ | $e4$ | $e5$ | $g5$ |
|---|---|---|---|---|---|---|---|---|---|---|

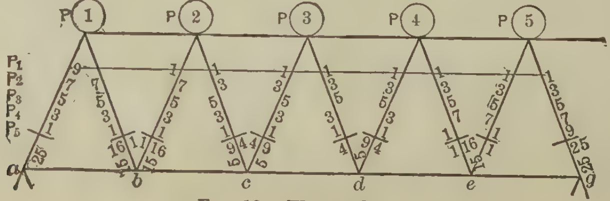

FIG. 10. Warren Girder

To determine the stress in any member, multiply net values as found above by $^1/_{10}$ of one of the loads as $P_1$ and by the secant of $^1/_2$ the angle between the diagonals. Stresses in horizontal chords may be determined by the method of moments. See p. 17–05.

**ROOF TRUSS.—Solution by Method of Moments.**—The calculation of stresses in structures by the method of statical moments consists in taking a cross-section of the structure at a point where there are not more than three members (struts, braces or chords). To find the stress in either one of these members take the moment about the intersection of the other two as an axis of rotation. The sum of the moment of these members must be zero if the structure is in equilibrium. But the moments of the two members that pass through the point of reference or axis are both zero, hence one equation containing one unknown quantity can be found for each cross-section.

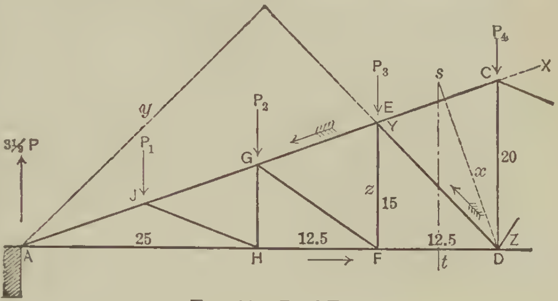

FIG. 11. Roof Truss

In the truss shown in Fig. 11, take a cross-section at $ts$ and determine the stress in the three members cut by it, *viz.*, $CE$, $ED$ and $DF$. Let $X$ = force exerted in direction $CE$, $Y$ = force exerted in direction $DE$, $Z$ = force exerted in direction $FD$.

Moment of $X$ about the intersection of $Y$ and $Z$ at $D = Xx$.
Moment of $Y$ about the intersection of $X$ and $Z$ at $A = Yy$
Moment of $Z$ about the intersection of $X$ and $Y$ at $E = Zz$.

Let $z = 15$; $x = 18.6$; $y = 38.4$; $AD = 50$ ft.; $CD = 20$ ft. Let $P_1$, $P_2$, $P_3$, $P_4$ be equal loads as shown, whence the reaction of abutment $A$ will be $3\,^1/_2\,P$. The sum of all moments about $D$, $A$, or $E$ will be zero when the structure is at rest. Moments in a clockwise direction are designated +; counter-clockwise moments are designated −.

Then $$-Xx + (3.5\,P \times 50) - (P_3 \times 12.5) - (P_2 \times 25) - (P_1 \times 37.5) = 0.$$

Since $$P = P_1 = P_2 = P_3, \quad \text{and} \quad x = 18.6,$$

$$-18.6\,X + 175\,P - 75\,P = 0, \quad \text{and} \quad X = 5.376\,P.$$

Similarly, $$-Yy + (P_3 \times 37.5) + (P_2 \times 25) + (P_1 \times 12.5) = 0, \quad \text{and} \quad Y = 1.953\,P.$$

$$-Zz + (3.5\,P \times 37.5) - (P_1 \times 25) - (P_2 \times 12.5) - (P_3 \times 0) = 0, \quad \text{and} \quad Z = 6.25\,P.$$

Stresses in the other members may be found in the same manner to be: $EG = 6.73\,P$; $GJ = 8.07\,P$; $JA = 9.42\,P$; $JH = 1.35\,P$; $GF = 1.59\,P$; $AH = 8.75\,P$; $HF = 7.50\,P$.

**ANALYSIS OF FINK ROOF TRUSS** (Fig. 12).—Let $W$ = total load on roof; $N$ = number of panels on both rafters; $W/N = P$ = load at each joint, $b$, $d$, $f$, etc.; $V$ = reaction at $A = {}^1/_2\,W = {}^1/_2\,NP = 4\,P$; $AD = S$; $AC = L$; $CD = D$; $t_1$, $t_2$, $t_3$ = tension in $De$, $eg$, $gA$, respectively; $C_1$, $C_2$, $C_3$, $C_4$ = compression in $Cb$, $bd$, $df$, and $fA$ respectively. Then the stresses in the several members will be:

| Member | Stress | Member | Stress | Member | Stress |
|---|---|---|---|---|---|
| 1 or $De$ | $t_1 = 2\,PS/D$ | 5 or $fd$ | $c_3 = {}^7/_2\,PL/D - PD/L$ | 9 or $de$ | $2\,PS/L$ |
| 2 " $eg$ | $t_2 = 3\,PS/D$ | 6 " $db$ | $c_2 = {}^7/_2\,PL/D - 2\,PD/L$ | 10 " $cd$ or $dg$ | ${}^1/_2\,PS/D$ |
| 3 " $gA$ | $t_3 = {}^7/_2\,PS/D$ | 7 " $bC$ | $c_1 = {}^7/_2\,PL/D - 3\,PD/L$ | 11 " $ec$ | $PS/D$ |
| 4 " $Af$ | $c_4 = {}^7/_2\,PL/D$ | 8 " $bc$ or $fg$ | $PS/L$ | 12 " $cC$ | ${}^3/_2\,PS/D$ |

EXAMPLE.—Find the stresses in the members of a Fink truss as shown in Fig. 12. Span 64 ft.;

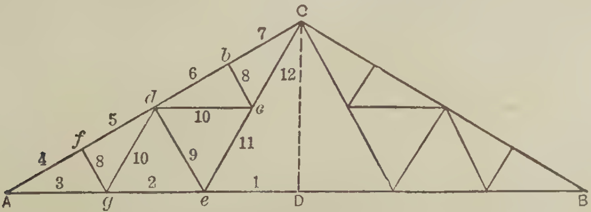

FIG. 12. Fink Roof Truss

depth, 16 ft.; 4 panels on each side; total load, 32 tons, or 4 tons each at points *f*, *d*, *b*, *C*, etc., and 2 tons each at *A* and *B*, which, however, transmit no stress to the truss members.

*Solution.*—$W = 32$; $P = 4$; $S = 32$; $D = 16$; $L = \sqrt{S^2 + D^2} = 2.236\,D$; $L/D = 2.236$; $D/L = 0.4472$; $S/D = 2$; $S/L = 0.8944$. Stresses in the members then are:

| Member | Stress | Member | Stress |
|---|---|---|---|
| 1 | 2 × 4 × 2 = 16 tons | 7 | 31.3 − (12 × 0.447) = 25.94 tons |
| 2 | 3 × 4 × 2 = 24 " | 8 | 4 × 0.8944 = 3.58 " |
| 3 | 7/2 × 4 × 2 = 28 " | 9 | 8 × 0.8944 = 7.16 " |
| 4 | 7/2 × 4 × 2.236 = 31.3 " | 10 | 2 × 2 = 4 " |
| 5 | 31.3 − (4 × 0.447) = 29.52 " | 11 | 4 × 2 = 8 " |
| 6 | 31.3 − (8 × 0.447) = 27.72 " | 12 | 6 × 2 = 12 " |

**GRAPHICAL ANALYSIS OF TRUSSES.**—The graphic method of determining stresses in truss members is applicable to any truss and any manner of loading; it is sufficiently accurate for practical purposes and the work can be done more quickly and with less danger of error than by the numerical method. The graphical method is based on the principle that straight lines drawn to scale to represent the magnitude and direction of forces acting on a point in equilibrium will form a closed polygon. By taking one joint of the truss after another the known external or internal forces acting at the joint are laid out and the unknown forces are determined by closing the polygon.

**Bow's Notation** is the most convenient method of designating areas, members and forces in graphical analyses. In this system, areas between truss members, members and external forces or between external forces are denoted by letters. Any member, panel load or reaction then may be designated by the two letters on each side. Thus in Fig. 13, *AH* represents the diagonal at the end of the truss, *AB* represents the panel load at the apex of the first panel *H*, and *HJ* represents the diagonal between panels *H* and *J*. When the stress diagram (Fig. 14) is drawn, the ends of a line representing the stress in a member or an external force are given the same letters used to denote the corresponding member or load in the truss diagram. Thus, in Fig. 14, the line *ab* represents the panel load *AB*, the line *ah* represents the stress in member *AH*, the line *ga* represents the reaction *GA*, etc.

**Procedure.**—1. Draw the truss diagram representing the truss members and indicate the points of application of all external forces acting on the truss including all loads applied at panel points and the reactions at points of support.

2. Determine, by computation, the vertical loads applied at the panel points and the reactions at points of support. If the panel loads are symmetrical with respect to the center of the span, both reactions are equal to half of the total load on the truss; if the truss is not loaded symmetrically the reactions are obtained by the method of moments.

3. Start the stress diagram (Fig. 14) on the same sheet of paper as the truss diagram, by drawing to scale the vertical load line *af* representing the total load; divide *af* so that lines *ab*, *bc*, *cd*, *de* and *ef* represent the corresponding panel loads. Locate point *g* so that *fg* and *ga* represent to scale the right and left reactions, respectively. In Fig. 13 the panel loads are assumed to be equal and, therefore, $fg = ga$. The polygon of forces acting on the truss is *a b c d e f g a*. The polygon must close as the truss is in equilibrium.

The stresses in the members are obtained in the stress diagram by laying out in clockwise order the forces acting at each joint of the truss, starting with the left reaction and constructing the force polygons for one joint after another until all the unknown stresses are determined. Thus in Fig. 14 the line *ga* represents the magnitude and direction of reaction *GA* in Fig. 13; by drawing lines through points *a* and *g* parallel to *AH* and *HG*, respectively, the force triangle *g a h g* is formed and lines *ga*, *ah* and *hg*, taken in order so as to close the force triangle, represent the direction and magnitude of reaction *GA* and stresses in *AH* and *HG*, respectively. The direction of these forces is indicated on the truss diagram by inserting arrows around the joint in members *AH* and *HG* pointing in the

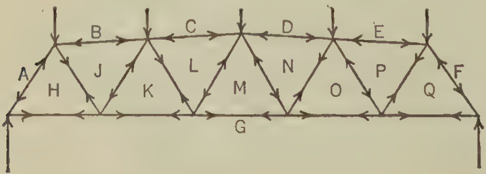

Fig. 13

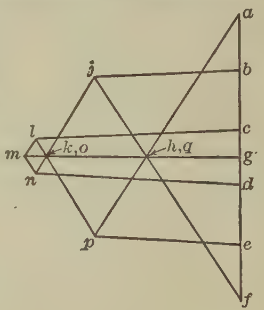

Fig. 14

directions taken by the corresponding stress lines in closing the triangle *g a h g*; therefore, in *AH* the arrow points toward, and in *HG* away from the joint. Next consider the forces acting at the left joint of the upper chord. The lines *ha* (just determined) and *ab* in Fig. 14 represent the magnitude and direction of the stress in *HA* and panel load *AB*, respectively; by drawing lines through *b* and *h* parallel to *BJ* and *JH*, respectively, the force polygon *h a b j h* is found and the lines *bj* and *jh* represent the magnitude and direction of stresses in the truss members *BJ* and *JH*. As before, the direction of forces acting at the joint considered is shown on the truss diagram by inserting arrows around the joint in all members pointing in the directions taken by the corresponding stress lines in closing the polygon *h a b j h*. Similarly, the remaining force polygons are constructed in the order given below to represent the forces acting at the joints indicated:

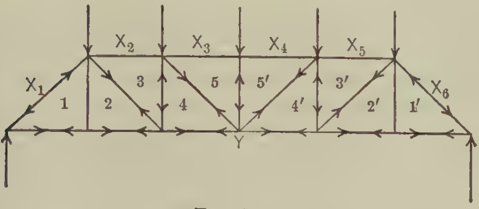

Fig. 15

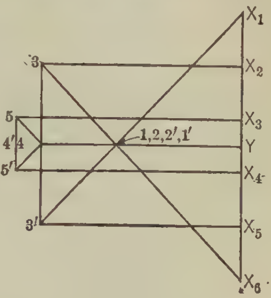

Fig. 16

| Order of Joints Considered | Polygon |
|---|---|
| 2d from left on lower chord | *g h j k g* |
| 2d from left on upper chord | *k j b c l k* |
| 3d from left on lower chord | *g k l m g* |
| 3d from left on upper chord | *m l c d n m* |
| 4th from left on lower chord | *g m n o g* |
| 4th from left on upper chord | *o n d e p o* |
| 5th from left on lower chord | *g o p q g* |
| 5th from left on upper chord | *q p e f q* |
| 6th from left on lower chord | *g q f g* |

At each of the above joints the magnitude and direction of at least two of the forces acting are determined from the polygon constructed for the preceding joint; the stress lines representing these are used as part of the polygon drawn to represent the forces acting at the joint considered.

It will be noted in the truss diagram that in those members where the arrows point toward each other, the stress in the member is tension; where the arrows point in opposite direction, the stress is compression.

The truss and stress diagrams for a six-panel Pratt truss are shown in Figs. 15 and 16, respectively, in which the notation used consists of letters and numbers. It will be noted that in Fig. 16, points 1, 2, 2′ and 1′ are coincident, and, therefore, the stress in verticals 1–2 and 1′–2′ is zero.

In both the Pratt and Warren trusses the end diagonals carry greater stresses than those nearer the center but in the upper and lower chords the members nearest the center carry greater stresses than the members nearer the supports.

**GRAPHICAL ANALYSIS OF TRUSSED BEAM.** (Figs. 17 and 19.)—A beam with rods underneath to take the tension may be considered as an inverted truss. The reactions are determined numerically by the method of moments (see p. 17–05), and the stress diagrams (Figs. 18 and 20) constructed in the same manner as outlined for a Warren or Pratt truss. When the load is suspended under the beam as in Fig. 19, the points *c* and *d* in the stress diagram are coincident and the stress in member *CD* is zero.

# BUILDING CONSTRUCTION

By Theodore Crane

## 1. FOUNDATIONS

**LOADS ON SOIL AND ROCK.**—Table 1 gives the maximum loads permitted on various foundation beds by four typical municipal ordinances. These are presumptive bearing capacities of different kinds of soil and rock, and form a guide to determine footing areas, but a most thorough investigation of sub-soil conditions also should be made. On important operations, actual loading tests should be made on the site.

**Table 1.—Maximum Loads on Soils and Rock Allowed by Various Building Ordinances**

| Foundation Bed | Loads in Tons per Square Foot | | | |
|---|---|---|---|---|
| | Boston | San Francisco | Philadelphia | New York |
| Soft clay | 2 * | 1 | 1 * | 1 |
| Fine grained wet sand | 3 * | 2 | 2 * | 2 |
| Dry, fine grained sand or hard clay | 4 | 3 or 4 | 4 | 3 or 4 |
| Coarse gravel without mica or clay | 6 | 6 | 6 | 6 |
| Shale and hardpan | 10 | 10 † | 8 | 10 |
| Medium rock | ... | ... | 24 | 15 |
| Hard rock | ... | 20 | 48 | 40 |
| Solid ledge rock | 100 | ... | ... | ... |

* Protected against lateral displacement, *i.e.*, confined. † Shale only.

When part of a building is supported on a yielding or compressible foundation bed and part on solid rock, the maximum bearing capacity of the soil should be taken at one-half the capacity otherwise allowed. A similar reduction may be advisable when part of the building is supported on piles and part on soil; the pile driving record should be studied before deciding, as the piles may be subject to settlement.

The area of the footing on hard-rock foundation beds is determined by the safe pressure on the concrete immediately above the rock, rather than by the bearing capacity of the rock. A compressive stress of 600 lb. per sq. in. in the concrete, corresponding to 43.2 tons per sq. ft., is the usual figure.

**PILES.**—Timber, concrete, steel tubular or caisson piles are used when suitable soil-bearing value cannot be had at an economic depth. Both timber and concrete piles may be driven to rock, or support their loads by skin friction. Steel piles are driven to bed rock and caisson piles are used to obtain the equivalent of a spread footing without excessive excavation. The first three types may be placed in a double row, preferably staggered beneath a wall, or in groups called *clusters* beneath column footings. The center of gravity of a cluster should coincide with that of the supported load or loads. Piles must not be so closely placed that the bearing capacity of the subsoil is exceeded.

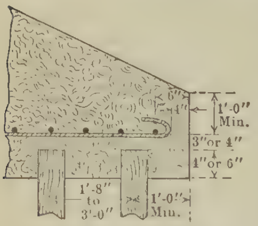

FIG. 1. Reinforced Concrete Footing on Timber Piles

**Timber Piles** may be either hard or soft wood, provided they are comparatively straight and do not split or broom excessively when driven. Minimum diameters are: 6 in. at small end; butt, 10 in. for piles under 25 ft. long, and 12 in. for longer piles; maximum butt diameter, 18 in. Spacing varies from 20 in. to 36 in. on centers. It is imperative that piles be cut off below permanent water level. Butts should extend 6 in. into the base of the superimposed footing. (See Fig. 1.)

**Safe Loads on Timber Piles** are given in the following equations:

$$\text{Pile driven by drop hammer, } P = 2\,Wh/(S + 1);$$

$$\text{Pile driven by single-acting steam hammer, } P = 2\,Wh/(S + 0.1),$$

where $P$ = safe load tons; $h$ = height of fall of hammer, ft.; $W$ = weight of hammer, tons, $S$ = penetration under the last blow, or average under last 5 blows of the hammer, in., provided that the driving has reached a point where successive blows produce approximately equal penetration, and that the maximum load is not over 20 tons.

**Concrete Piles** are desirable if high bearing capacity is required. They may extend above ground-water level, and often effect savings in excavation and foundation cost. Spacing usually is about 3 ft. centers. Concrete piles either may be cast in place or molded before driving. The minimum diameter or lateral dimension of precast piles is 8 in. at the point; average, 12 in. minimum; diameter, at the point, of piles molded in place, 6 in. minimum. The allowable sustaining power, when driven to rock, varies with type of pile employed, but is based on a compressive stress varying from 350 to 500 lb. per sq. in. on the concrete at the average cross-section plus 5000 to 6000 lb. per sq. in. on the vertical reinforcement. When not driven to rock, sustaining power usually is determined by test; in any case, the load on a single pile is limited to 30 or 40 tons.

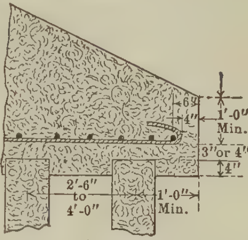

Fig. 2. Reinforced Concrete Footing on Reinforced Concrete Piles

**Steel Tubular Piles** which are filled with concrete after driving usually are 9 in. diam. with a minimum shell thickness of $^5/_{16}$ in. They ordinarily are driven to a full bearing on rock. Bearing capacity may be taken as 500 lb. per sq. in. on the concrete, and 7500 lb. per sq. in. on the steel, disregarding the outer $^1/_{16}$ in. of the shell. Maximum length of such piles is (40 × inside diam. of tube).

**Caisson Piles,** of short, sheet-steel cylinder sections, are sunk by their own weight as earth is dug from below the cutting edge, and later are filled with concrete. The shafts are 36 in. diameter. The base is bell-shaped to provide the required bearing area. Caisson piles can carry the entire weight of a heavily loaded column.

## Footings

**WALL FOOTINGS** under curtain walls and for low buildings of bearing-wall construction, are usually of plain concrete. To determine the width, divide load per linear foot of wall by bearing capacity of the soil; minimum projection on each side of the wall is 6 in. Such footings are constructed either as a slab or with steps. Minimum thickness of bottom block = 12 in.; when stepped, maximum projection of each block is one-half its height. If loads are heavy in proportion to allowable soil pressure, reinforcement may be used in the footing slab. The overhanging portion of each course is designed as a cantilever to resist bending moment and shear caused by upward thrust due to soil pressure.

**FOOTINGS FOR EXTERIOR AND INTERIOR COLUMNS** usually are of reinforced concrete; steel girder footings are occasionally used. Steel slabs or grillages, the latter built of steel beams, are used under heavily loaded columns to distribute the load over a reinforced concrete footing or rock foundation bed. The beams are placed side by side and enclosed in concrete. The protective covering varies from 4 to 8 in.

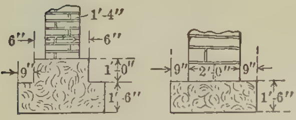

Fig. 3. Alternate Designs for Wall Footings

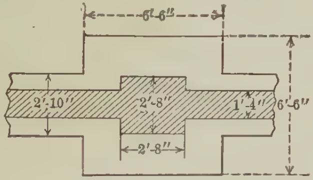

Fig. 4. Footing Below Masonry Pier

With extremely low soil capacities, a reinforced concrete mat over the entire basement of a building may be necessary to utilize all the available area. A mat is designed by the methods used for beam-and-slab or girderless floors, taking the soil reaction as superimposed load. Present practice (1937) favors plain concrete footings for walls and lightly loaded columns. Column footings projecting 18 in. or more beyond the face of column, usually are more economical if reinforced. Steel grillage footings are seldom used except under high buildings resting upon a foundation bed of rock.

For design formulas for reinforced concrete footings and slabs, see Eshbach, Handbook of Engineering Fundamentals, Section 5, forming Vol. 1 of this series.

**PROPORTIONMENT OF FOOTING AREA.**—To equalize the settlements of different parts of a structure resting on a compressible foundation bed, the unit soil pressure should be the same under all footings where soil conditions are similar. Settling of a building is gradual, often long continued, and results from constant dead loads rather

(*Continued on page* 17–13)

| Sidewalks | 300 | 120 | 250 | 150 | 150 | 250 |

* Building Code Committee of the Bureau of Standards, U. S. Dept. of Commerce.

than occasional live loads. While footing areas must be large enough to avoid a possibility of total live and dead loads exceeding the allowable pressure on the foundation bed, areas must be proportioned on a basis of full dead loads and a percentage of live loads representing probable conditions of occupancy. Divide the sum of the dead load and assumed percentage of live load by the area of the footing having the largest ratio of live to dead load, to obtain the average unit pressure. This average is used to find the size of the remaining footings; in each case use the full dead load plus the assumed percentage of live load.

The following is recommended as a basis for proportioning footing areas for various kinds of buildings:

1. Office buildings, apartment houses, hotels, and schools, *Dead Loads Only;*
2. Industrial buildings for light manufacturing, Dead Load + (0.20 × Live Load);
3. Industrial buildings for heavy manufacturing, with partial storage, Dead Load + (0.40 × Live Load);
4. Warehouses and buildings for storage purposes, Dead Load + (0.60 × Live Load).

**CAISSON AND OPEN-WELL FOUNDATIONS.**—When necessary to carry deep foundations to rock, and below the depth which can be excavated economically, the open-well method may be used if the character of the successive strata of subsoil will permit excavation without compressed air. If character of the soil or pressure of large quantities of water makes this impracticable, pneumatic caissons are used. In either case shafts are later filled with concrete.

## 2. STRUCTURAL DESIGN

**BUILDING ORDINANCES.**—All cities control design of both structural steel and reinforced concrete, by imposing limiting stresses, and by arbitrary limitations in size of structural members and fireproofing requirements. Also, all features concerning fire hazards, or working conditions of the employees, generally are governed by municipal ordinance or State industrial codes. Typical restrictions of this kind, affecting design of industrial work, are the types of buildings in specified zones, height and area limitations, minimum requirements for light and ventilation according to type of occupancy, specifications of materials. The Underwriters' label has become practically a universal standard for all manufactured parts or devices, whose character affects fire risk or safety of occupants in case of fire.

**WORKING STRESSES.**—For steel structures, see Specifications for Structural Steel for Buildings, p. 17–14; for reinforced concrete structures, see Eshbach, Handbook of Engineering Fundamentals, Section 5, forming Vol. 1 of this series.

**SOIL LOADS AND LIVE LOADS** for different types of occupancy, together with weights to be assumed for various materials when computing dead loads, are given in Tables 1, 2 and 3.

**LIVE LOAD REDUCTIONS** may be permitted, for buildings for other than storage purposes, when designing supporting members carrying more than one floor. For example, when computing column sizes for a multi-story building, 100% of the live load is used for the roof and top floor, 90% for next floor below, and correspond decreases for lower floors, but, in no case, less than 50%.

**WIND LOADS.**—See Specification for Structural Steel for Buildings (p. 17–14). The same values may be used for reinforced concrete structures.

**SNOW LOADS** may be taken at 30 lb. per sq. ft. of horizontal projection for slopes up to 20°. Above a 45° slope no snow load need to be considered. For slopes between 20° and 45° the load should be proportionately reduced.

**IMPACT OR DYNAMIC LOADS.**—See p. 7–15.

**ARBITRARY REQUIREMENTS** controlling the thickness of walls and floors, the slenderness ratio of columns, and the maximum unsupported lengths of walls and partitions, are in every building ordinance. Such regulations often control dimensions of structural members, even if actual stresses are less than stipulated by the code.

**FIREPROOFING REQUIREMENTS** for iron or steel require a 3 $^3/_4$ in. thickness of brick, 4 in. of hollow clay tile, or 2 in. of concrete or solid gypsum for columns, and at least 1 $^1/_2$ in. of concrete, or equivalent insulation, for beams and girders.

**EXIT REQUIREMENTS** are important as affecting the plan of a building. Every room of area exceeding 1000 sq. ft., or occupied by more than 75 persons should have at least two doorways, remote from each other, each being a direct exit or furnishing unobstructed egress through other rooms. Every floor area with direct exit to a street, occupied by more than 75 persons, should have at least two exits. Every story without direct exit to the street should have at least one interior stairway or fire tower connected thereto, and at least one additional exit if its area exceeds 2500 sq. ft. Buildings over 60 ft high, except when sprinklered, should have at least one stairway constructed as a fire tower. A fire tower ordinarily is not required if there are two stairways and the structure is not over 100 ft. high, and is sprinklered.

Stairways should be of adequate width to meet conditions of occupancy; at least 44 in. wide when used as legal exits for industrial buildings, and 36 in. wide for storage buildings; the width of standard handrails may be deducted. Stairwells 8 ft. wide between terra cotta or other masonry surfaces provide for up and down runs from intermediate landings which are as wide as the stairs. Minimum width of stair treads usually is 9 1/2 in.; maximum height of risers usually is 7 3/4 in. The product (tread × riser) should be 70 to 75.

## 3. BUILDING FRAMES

Structural steel and reinforced concrete are universally used for frames of fire-resistant buildings. Steel generally is more suitable for structures supporting comparatively light live loads or over 20 stories high. Reinforced concrete is suitable for comparatively low buildings sustaining heavy live loads, and for certain types of monumental buildings of moderate height. For multi-story garages, warehouses and industrial buildings, concrete usually is more satisfactory. For the one-story garage, hangar or manufacturing plant, steel-frame construction is more economical.

For apartment houses, hotels, hospitals and most institutions, four stories high or more, either reinforced concrete or steel may be better, depending on local conditions. Both types of frame usually are enclosed by a veneer; as the architectural appearance is the same in either case, the choice between steel and concrete may be made on a purely economic basis.

Columns of a steel frame usually are H-sections, continuous through two stories, and often reinforced with plates through the lower stories. Built-up columns seldom are used on typical construction. Floors are supported by girder-beams or I-beams, unless the length of span or the amount of load requires plate girders or trusses. Spandrel beams at each story carry wall loads to the columns. The various floor systems appropriate for steel and concrete frames are described on page 17–24.

### Specifications for the Design, Fabrication, and Erection of Structural Steel for Buildings *

**1. MATERIALS.**—*a.* Structural steel shall conform to A.S.T.M. standard specifications for steel for buildings (serial designation A9) as amended to date. *b.* Rivet steel shall conform to A.S.T.M. standard specifications for structural rivet steel (serial designation A 141) as amended to date. *c.* Alloy steels, cast steel, cast iron and other metals shall conform to the applicable specifications of the A.S.T.M. as amended to date. *d.* Stock material shall be of quality substantially equal to that called for by specifications of the A.S.T.M. for classifications covering its intended use; and mill test reports shall constitute sufficient record as to quality of material carried in stock. Unidentified stock material, if free from surface imperfections, may be used for short sections of minor importance, or for small unimportant details, where the precise physical properties of the material would not affect the strength of the structure.

**2. LOADS AND FORCES.**—Steel structures shall be designed to sustain the following loads and forces: Dead load, live load, impact, wind, erection loads, and other forces. *a.* The dead load shall consist of the weight of steel-work and all material fastened thereto or supported thereby. *b.* The live load shall be that stipulated by the Code under which the structure is designed or that required by conditions involved. In general, the live loads should not be less than those recommended by the Building Code Committee of the National Bureau of Standards, November, 1924, under the caption "Minimum Live Loads for Use in the Design of Buildings." *c.* For structures, carrying live loads, inducing impact or vibrational forces, design stresses shall be increased by a percentage of the live load stresses sufficient to provide for such forces. *d.* Proper provision shall be made for stresses caused by wind, both during erection and after completion of building. Wind pressure is dependent on conditions of exposure and geographical location. Allowable stresses specified in Sections 4c and 5 are based on the steel frame being designed to carry a wind pressure of not less than 20 lb. per sq. ft. on the vertical projection of exposed surfaces during erection, and 15 lb. per sq. ft. on the vertical projection of the finished structure. *e.* Proper provision shall be made for temporary stresses caused by erection. *f.* Structures in localities subject to earthquakes, hurricanes, and similar extraordinary conditions, shall be designed with due regard for such conditions.

**3. REVERSAL OF STRESS.**—Members subject to live loads producing alternate tensile and compressive stresses shall be proportioned as follows: To net total compressive and tensile stresses add 50% of the smaller of the two, and proportion the member to resist either of the increased stresses resulting therefrom. Connections shall be proportioned to resist the larger of the two increased stresses.

---

* Abstracted from Specifications of Am. Inst. of Steel Construction, revised 1936.

**4. COMBINED STRESSES.**—*a.* Members subject to both axial and bending stresses shall be so proportioned that the quantity $\{(f_a/F_a) + (f_b/F_b)\}$ shall not exceed unity, in which $F_a$ = axial unit stress that would be permitted by this Specification if axial stress only existed; $F_b$ = bending unit stress that would be permitted by this Specification if bending stress only existed; $f_a$ = axial unit stress (actual) = axial stress divided by area of member; $f_b$ = bending unit stress (actual) = bending moment divided by section modulus of member. *b.* Rivets subject to shearing and tensile forces shall be so proportioned that the combined unit stress will not exceed the allowable unit stress for rivets in tension only. *c.* Members subject to stresses produced by a combination of wind and other loads may be proportioned for unit stresses 33 1/3% greater than those specified in Section 7, provided the section thus required is not less than that required for the combination of dead load, live load, and impact (if any).

**5. MEMBERS CARRYING WIND ONLY.**—Members subject only to stresses produced by wind forces may be proportioned for unit stresses 33 1/3% greater than those specified in Section 7.

**6. EFFECTIVE SPAN LENGTH.**—*a.* Beams, girders and trusses ordinarily shall be designed on the basis of simple spans whose effective length is equal to the distance between centers of gravity of the members to which they deliver their end reactions. *b.* If, on the assumption of end restraint, full or partial, based on continuous or cantilever action, beams, girders and trusses are designed for a shorter effective span length than that specified in Section 6*a*, their sections, as well as the sections of the members to which they connect, shall be designed to carry the shears and moments so introduced, in addition to all other forces, without exceeding at any point the unit stresses prescribed in Section 7.

**7. ALLOWABLE UNIT STRESSES.**—All parts of the structure shall be so proportioned that the unit stress in lb. per sq. in. shall not exceed the following:

*a.* **Structural and Rivet Steel**

| | | |
|---|---|---|
| **Tension.** | Structural steel, net section | 20,000 |
| | Rivets, on area based on nominal diameter | 15,000 |
| **Compression.*** | Columns, gross section, $(l/r) \not> 120$ | $17{,}000 - 0.485\,(l^2/r^2)$ |
| | Columns, gross section, $(l/r) > 120$ | $18{,}000/\{1 + (l^2/18{,}000\,r^2)\}$ |
| | Plate girder stiffeners, gross section | 20,000 |
| | Webs of rolled sections at toe of fillet (Crippling, see Section 16*h*) | 24,000 |
| **Bending.*** | Tension on extreme fibers of rolled sections, plate girders, and built-up members (see Section 16*a*) | 20,000 |
| | Compression on extreme fibers of rolled sections, plate girders, and built-up members, for values of $l/b \not> 40$ | $22{,}500/\{1 + (l^2/18{,}000\,b^2)\}$ |
| | Maximum | 20,000 |
| | Stress on extreme fibers of pins | 30,000 |
| **Shearing.** | Rivets, pins, and turned bolts in reamed or drilled holes | 15,000 |
| | Unfinished bolts | 10,000 |
| | Webs of beams and plate girders, gross section | 13,000 |

| | | Double Shear | Single Shear |
|---|---|---|---|
| **Bearing.** | Rivets and turned bolts in reamed or drilled holes | 40,000 | 32,000 |
| | Unfinished bolts | 25,000 | 20,000 |
| | Pins | 32,000 | |
| | Contact area, milled stiffeners and other milled surfaces | | 30,000 |
| | Fitted stiffeners | | 27,000 |
| | Expansion rollers and rockers, lb. per lin. in. | | 600 *d* |

*b.* **Cast Steel.**—Compression and bearing same as structural steel.
Other unit stresses 75% of those for structural steel.

*c.* **Masonry** (**Bearing**).—Granite 800; sandstone and limestone 400; concrete 600.

**8. SLENDERNESS RATIO.**—The ratio of unbraced length to least radius of gyration $(l/r)$ for compression members shall $\not>$ 120 for main compression members, and 200 for bracing and other secondary compression members.

**9. UNSUPPORTED COMPRESSION FLANGES.**—The ratio of unbraced length to width of flange $(l/b)$ for compression flanges of rolled sections, plate girders, and built-up members subject to bending shall $\not>$ 40.

**10. MINIMUM THICKNESS OF MATERIAL.**—*a.* The minimum thickness of steel except for linings, filler, and webs of rolled beams and channels, shall be: For exterior construction 5/16 in.; for interior construction 1/4 in. (These provisions do not apply to light structures such as skylights, marquees, fire-escapes, light one-story buildings, or light miscellaneous steel-work.) *b.* Gusset plates for trusses with end reactions > 35,000 lb. shall $\not<$ 3/8 in. *c.* In compression members consisting of segments connected by cover plates or lacing, or segments connected by webs, the thickness of webs of segments shall $\not<$ 1/32 of the unsupported distance between the nearest rivet lines, or roots of the flanges in case of rolled section. The thickness of cover plates or webs connecting segments shall $\not<$ 1/40 of the unsupported distance between the nearest lines of their connecting rivets, or roots of their flanges in case of rolled sections. *d.* Provision shall be made for parts subject to corrosive agents either by increasing the thickness of material or by effective protection.

---

* Notation for the formulas in this specification is as follows: $l$ = unbraced length, in.; $r$ = radius of gyration, in.; $b$ = width of compression flange, in.; $d$ = diameter of roller or rocker, in.

**11. GROSS AND NET SECTIONS.**—*a.* The gross section of a member at any point shall be determined by summing the products of thickness and gross width of each element, measured normal to the axis of the member. The net section shall be determined by substituting for gross width, the net width computed in accordance with paragraphs *c* to *g* of this Section. *b.* Unless otherwise specified, tension members shall be designed on the basis of net section. Columns shall be designed on the basis of gross section. Beams and girders shall be designed in accordance with Section 16 *a.* *c.* In the case of a chain of holes extending across a part in any diagonal or zigzag line, the net width of the part shall be obtained by deducting from the gross width the sum of diameters of all holes in the chain, and adding, for each gage space in the chain, the quantity $(S^2/4g)$.* The critical net section of the part is obtained from that chain which gives the least net width. *d.* For angles, the gross width shall be the sum of the widths of legs less the thickness. The gage for holes in opposite legs shall be sum of the gages from back of angle less the thickness. *e.* For splice members, the thickness shall be only that part of the thickness of member which has been developed by rivets beyond the section considered. *f.* In computing net area the diameter of a rivet hole shall be taken as $1/8$ in. greater than the nominal diameter of rivet. *g.* In pin-connected tension members, the net section across the pin hole, transverse to the axis of member, shall $\geqq$ 140%, and the net section beyond the pin hole, parallel with the axis of the member shall $\geqq$ 100%, of the net section of the body of member. In all pin-connected riveted members, the net width across the pin hole, transverse to the axis of the member, shall preferably not exceed (12 × thickness of member at the pin).

**12. EXPANSION.**—Proper provision shall be made for expansion and contraction.

**13. CONNECTIONS.**—*a.* Connections carrying calculated stresses, except for lacing, sag bars, and girts, shall have not fewer than 2 rivets. *b.* Members meeting at a point shall have their gravity axes meet at a point if practicable; if not, provision shall be made for their eccentricity. *c.* The rivets at the ends of any member transmitting stresses into that member preferably should have their centers of gravity on the gravity axis of the member; otherwise, provision shall be made for the effect of the resulting eccentricity. Pins may be so placed as to counteract the effect of bending due to dead load. *d.* When beams, girders or trusses are designed on the basis of simple spans in accordance with Section 6*a*, their end connections ordinarily may be designed for the reaction shears only. If, however, the eccentricity of the connection is excessive, provision shall be made for the resulting moment. *e.* When beams, girders or trusses are subject both to reaction, shear and end moment, due to the restraint specified in Section 6*b*, their connections shall be specially designed to carry both shear and moment without exceeding at any point the unit stresses prescribed in Section 7. Ordinary end connections comprising only a pair of web angles, with not more than a nominal seat and top angle, shall not be assumed to provide for this kind of end moment. *f.* In truss construction, when rivets carrying computed stress pass through fillers, the fillers shall be extended beyond connected member and extension secured by sufficient rivets to develop strength of filler. Fillers under plate girder stiffeners at end bearings or points of concentrated loads shall be secured by sufficient rivets to prevent excessive bending and bearing stresses. *g.* Compression members when faced for bearings shall be spliced sufficiently to hold connecting members accurately in place. Other joints in riveted work, whether in tension or compression, shall be spliced to transfer the stress to which the member is subject.

**14. RIVETS AND BOLTS.**—*a.* In proportioning rivets, the nominal diameter of the rivet shall be used. *b.* The effective bearing area of pins, bolts, and rivets shall be the diameter multiplied by the length in bearing; except that for countersunk rivets, half the depth of the countersink shall be deducted. *c.* Rivets carrying calculated stress, and whose grip exceeds five diameters, shall have their number increased 1% for each additional $1/16$ in. in the rivet grip. Special care shall be used in heating and driving such rivets. *d.* All field connections may be made with unfinished bolts, except as provided in *e* hereof. *e.* Rivets shall be used for the following connections: Connections for supports of running machinery, or of other live loads which produce impact or reversal; column splices in all tier structures 200 ft. high or more; column splices in tier structures 100 to 200 ft. high, if the least horizontal dimension is < 40% of the height; column splices in tier structures less than 100 ft. high, if the least horizontal dimension is < 25% of the height; connections of all beams and girders to columns, and of any other beams and girders on which the bracing of columns is dependent, in structures over 125 ft. high; roof-truss splices and connections of trusses to columns, column splices, column bracing, and crane supports, in all structures carrying cranes of over 5-ton capacity; any other connections stipulated on the design plans. The height of a tier structure shall be taken as the vertical distance from the curb level to the highest point of the roof beams, in the case of flat roofs, or to the mean height of the gable, in the case of roofs having a rise of more than 1 to a 4 1/2 run. Where the curb level has not been established, or where the structure does not adjoin a street, the mean level of the adjoining land shall be used instead of curb level. Penthouses may be excluded in computing height of structure. *f.* Turned bolts in reamed or drilled holes, as specified in Section 22*d* may be used in shop or field work where it is impossible to drive satisfactory rivets. The finished shank shall be long enough to provide full bearing, and washers shall be used under the nuts to give full grip when the nuts are turned tight. *g.* The end reaction stresses of trusses, girders, or beams, and the axial stresses of tension or compression members which are carried on rivets or bolts, shall have such stresses developed by the shearing and bearing values of the rivets or bolts.

**15. RIVET SPACING.**—*a.* The minimum distance between centers of rivet holes shall be three diameters of the rivet; but the distance shall preferably be not less than 4 1/2 in. for 1 1/4-in. rivets, 4 in. for 1 1/8-in. rivets, 3 1/2 in. for 1-in. rivets, 3 in. for 7/8-in. rivets, 2 1/2 in. for 3/4-in. rivets, 2 in.

---

* $s$ = longitudinal spacing (pitch) of any two successive holes. $g$ = transverse spacing (gage) of the same two holes.

for $5/8$-in. rivets, and 1 $3/4$ in. for $1/2$-in. rivets. *b.* The maximum pitch in the line of stress of compression members composed of plates and shapes shall not exceed (16 × thickness of the thinnest outside plate or shape), nor (20 × thinnest enclosed plate or shape), with a maximum of 12 in., and the distance between lines of rivets, at right angles to the direction of stress, shall not exceed (30 × thickness of the thinnest plate or shape). For angles in built sections with two gage lines, with rivets staggered, the maximum pitch in the line of stress in each gage line shall not exceed (24 × thickness of the thinnest plate), with a maximum of 18 in. *c.* The pitch of rivets at the ends of built compression members shall not exceed 4 diameters of the rivets for a length equal to (1 $1/2$ × maximum width of the member). *d.* In tension members composed of two angles, a pitch of 42 in. will be allowed, and in compression members, 24 in., but the ratio $l/r$ for each angle between the rivets shall be not more than $3/4$ of that for the whole member. *e.* The minimum distance from the center of any punched rivet hole to any edge shall be that given in Table A.

**Table A.—Minimum Rivet Distances**

| Rivet diameter, in. | 1/2 | 5/8 | 3/4 | 7/8 | 1 | 1 1/8 | 1 1/4 |
|---|---|---|---|---|---|---|---|
| Min. edge distance for punched holes, in. | | | | | | | |
| In sheared edge | 1 | 1 1/8 | 1 1/4 | 1 1/2 | 1 3/4 | 2 | 2 1/4 |
| In rolled edge, sections with parallel flanges | 7/8 | 1 | 1 1/8 | 1 1/4 | 1 1/2 | 1 3/4 | 2 |
| In rolled edge, sections with sloping flanges | 3/4* | 7/8* | 1* | 1 1/8* | 1 1/4 | 1 1/2* | 1 3/4* |

* May be decreased $1/8$ in. when holes are near end of beam.

*f.* The distance from center of any rivet under computed stress, and that end or other boundary of the connected member toward which the pressure of the rivet is directed, shall $\geqq$ the shearing area of the rivet shank (single or double shear respectively) divided by the plate thickness. This end distance may however be decreased in such proportion as the stress per rivet is less than that permitted under Section 7*a*; and the requirement may be disregarded if the rivet in question is one of three or more in a line parallel to the direction of stress. *g.* The maximum distance from the center of any rivet to the near edge shall be (12 × thickness of plate), but shall not exceed 6 in.

**16. PLATE GIRDERS AND ROLLED BEAMS.**—*a.* Riveted plate girders, cover-plated beams, and rolled beams shall, in general, be proportioned by the moment of inertia of the gross section. No deduction shall be made for standard shop or field rivet holes in either flange; except that in special cases where the reduction of the area of either flange by such rivet holes, calculated in accordance with the provisions of Section 11, exceeds 15% of the gross flange area, the excess shall be deducted. If such members contain other holes, as for bolts, pins, or countersunk rivets, the full deduction for such holes shall be made. The deductions thus applicable to either flange shall be made also for the opposite flange if the corresponding holes are there present. *b.* Plate girder webs shall have a thickness $\geqq 1/170$ of the unsupported distance between flanges. *c.* Cover plates, when required, shall be equal in thickness or shall diminish in thickness from the flange angles outward. No plate shall be thicker than the flange angles. Unstiffened cover plates shall not extend more than 6 in. nor more than (12 × thickness of the thinnest plate) beyond the outer row of rivets connecting them to the angles. *d.* Rivets connecting flanges to the web shall be proportioned to resist the horizontal shear due to bending as well as any loads applied directly to the flange. *e.* Stiffeners shall be placed on the webs of plate girders at the ends and at points of concentrated loads. Such stiffeners shall have a close bearing against the flanges, shall extend as closely as possible to the edge of the flange angles, and shall not be crimped. They shall be connected to the web by enough rivets to transmit the stress. Only that portion of the outstanding legs outside of the fillets of the flange angles shall be considered effective in bearing. Intermediate stiffeners shall be required at all points where $h/t$ exceeds $(8000/\sqrt{s})$; $h$ = clear depth between flanges, in.; $t$ = thickness of web, in.; $s$ = greatest unit shear in panel, lb. per sq. in., under any condition of complete or partial loading. The clear distance between intermediate stiffeners, when stiffeners are required by the foregoing, shall not exceed 84 in. or that given by the formula $d = (270{,}000\,t/s)\sqrt[3]{st/h}$; $d$ = clear distance between stiffeners, in. Intermediate stiffeners may be crimped over the flange angles. Plate girder stiffeners shall be in pairs, one on each side of the web, and shall be connected to the web by rivets spaced not more than (8 × their nominal diameter). *f.* Web splices in plate girders shall be proportioned to transmit the full shearing and bending stresses in the web at the point of splice. Flange splices shall be proportioned to develop full strength of the members cut. *g.* Flanges of plate girders supporting cranes or other moving loads shall be proportioned to resist any lateral forces produced by such loads. *h.* Rolled beams shall be so proportioned that the compression stress at the web toe of the fillets, resulting from concentrated loads, shall not exceed the value of 24,000 lb. per sq. in. allowed in Section 7.

The governing formulas shall be:

For interior loads $R/t(A + 2N) \leqq 24{,}000$;

For end reactions $R/t(A + N) \leqq 24{,}000$;

$R$ = concentrated interior load or end reactions, in.-lb.; $t$ = thickness of web. in.; $A$ = length of bearing, in.; $N$ = distance from outer face of flange to web toe of fillet, in.

**17. TIE PLATES.**—*a.* Open sides of compression members shall be provided with lacing having tie plates at each end, and at intermediate points if lacing is interrupted. Tie plates shall be as near the ends as practicable. In main members carrying calculated stresses end tie plates shall have a length $\geqq$ distance between lines of rivets connecting them to the segments of the member, and intermediate ones $\geqq 1/2$ this distance. Thickness of tie plates shall $\geqq 1/50$ of distance between lines of rivets connecting them to the segments of the members, and the rivet pitch shall be ⋝ 4 diameters. Tie plates shall be connected to each segment by at least 3 rivets. *b.* Tie plates shall be used to secure the parts of tension members composed of shapes. They shall have a length ⋝ 2/3 of the length specified for tie plates in compression members. The thickness shall ⋝ 1/50 of the distance between the lines of rivets connecting them to the segments of the member and they shall be connected to each segment by at least 3 rivets.

**18. LACING.**—*a.* Lacing bars of compression members shall be so spaced that the ratio $l/r$ of the flange included between their connections shall ⋜ 3/4 of that of the member as a whole. *b.* Lacing bars shall be proportioned to resist a shearing stress normal to axis of member equal to 2% of the total compressive stress in the member. In determining the section required, the compression formula shall be used, $l$ being taken as the length of the bar between the outside rivets connecting it to the segment for single lacing and 70% of that distance for double lacing. The ratio $l/r$ shall ⋜ 140 for single lacing and 200 for double lacing. *c.* The thickness of lacing bars shall for single lacing ⋝ 1/40, and for double lacing shall ⋝ the distance between end rivets; their minimum width shall be (3 × diameter of rivets connecting them to the segments). *d.* The inclination of lacing bars to the axis of members preferably shall ⋝ 45° for double lacing and 60° for single lacing. When the distance between the rivet lines in the flanges > 15 in. the lacing shall be double and riveted at the intersection if bars are used, or else shall be made of angles.

**19. ADJUSTABLE MEMBERS.**—The total initial stress in adjustable members shall be assumed as ⋝ 5000 lb.

**20. COLUMN BASES.**—*a.* Provision shall be made to transfer the column loads, and moments if any, to footings and foundations. *b.* Column bases shall be set level and to correct elevation, with full bearing on masonry. *c.* Column bases shall be finished to accord with following: 1. Rolled steel bearing plates, 2 in. or less thick, may be used without planing, provided a satisfactory contact bearing is obtained; rolled steel bearing plates, over 2 in., but 4 in. or less thick, may be straightened by pressing (planed on all bearing surfaces if presses are not available) to obtain a satisfactory contact bearing; rolled steel bearing plates, over 4 in. thick, shall be planed on all bearing surfaces (except as noted under 3). 2. Column bases, other than rolled steel bearing plates, shall be planed on all bearing surfaces (except as noted under 3). 3. Bottom surfaces of bearing plates and column bases which rest on masonry foundations and are grouted to insure full bearing contact need not be planed.

**21. ANCHOR BOLTS.**—Anchor bolts shall be of sufficient size and number to develop the computed stress.

**22. WORKMANSHIP.**—*a.* All workmanship shall be equal to the best practice in modern structural shops. *b.* All material shall be clean and straight. If straightening or flattening is necessary, it shall be done by a process and in a manner that will not injure the material. Sharp kinks or bends shall be cause for rejection. *c.* Rolled sections, except for minor details, preferably shall not be heated, or, if heated, shall be annealed, but this restriction does not apply to gas cutting, Section 22*l*. *d.* Holes for rivets or unfinished bolts shall be 1/16 in. larger than the nominal diameter of the rivet or bolt. If the thickness of the material is not greater than the nominal diameter of the rivet or bolt plus 1/8 in., the holes may be punched. If the thickness of the material is greater than the nominal diameter of the rivet or bolt plus 1/8 in., the holes either shall be drilled from the solid, or sub-punched and reamed. The die for all sub-punched holes, and the drill for all sub-drilled holes, shall be 1/16 in. smaller than the nominal diameter of the rivet or bolt. Holes for turned bolts shall be 1/50 in. larger than the external diameter of the bolt. If the bolts are to be inserted in the shop, the holes either may be drilled from the solid, or sub-punched and reamed. If the bolts are to be inserted in the field, the holes shall be sub-punched in the shop and reamed in the field. All drilling or reaming for turned bolts shall be done after the parts to be connected are assembled. Drifting to enlarge unfair holes shall not be permitted. Holes that must be enlarged to admit the rivets shall be reamed. Poor matching of holes shall be cause for rejection. *e.* Planing or finishing of sheared plates or shapes will not be required unless specifically called for on the drawings. *f.* All parts of riveted members shall be well pinned or bolted and rigidly held together while riveting. Drifting done during assembling shall not distort the metal or enlarge the holes. *g.* All rivets are to be power-driven hot. Rivets driven by pneumatically- or electrically-operated hammers are considered power-driven. Standard rivet heads shall be of approximately hemi-spherical shape and of uniform size throughout the work for the same size rivet, full, neatly finished, and concentric with the holes. Rivets after driving, shall be tight, completely filling the holes, and with heads in full contact with the surface. Rivets shall be heated uniformly to a temperature not exceeding 1950° F.; they shall not be driven after their temperature is below 1000° F. Loose, burned, or otherwise defective rivets shall be replaced. *h.* Compression joints depending on contact bearing shall have the bearing surfaces truly machined to a common plane after the members are riveted. All other joints shall be cut straight. *i.* Ends of lacing bars shall be neat and free from burrs. *j.* Finished members shall be true to line and free from twists, bends and open joints. Compression members may have a lateral variation ⋜ 1/1000 of the axial length between points which are to be laterally supported. A variation of 1/32 in. is permissible in the overall length of members with both ends milled. Members without milled ends which are to be framed to other steel parts of the structure may have a variation from the detailed length not greater than 1/16 in. for members 30 ft. long or less, and not greater than 1/8 in. for members over 30 ft. long. *k.* All steel castings shall be annealed. *l.* The use of a cutting torch is permissible if the metal being cut is not carrying stresses during the operation. To determine the effective width of members so cut, 1/8 in. shall be deducted from each gas-cut edge. The radius of re-entrant gas-cut fillets shall be as large as practicable, but never less than 1 in.

**23. SHOP PAINTING.**—*a.* Before leaving the shop, all steel-work shall be thoroughly cleaned, by effective means, of all loose mill scale, rust and foreign matter. Except where encased in concrete, all steel-work shall be given one coat of approved metal protection, applied thoroughly and evenly and well worked into the joints and other open spaces. All paint shall be applied to dry surfaces. *b.* Parts inaccessible after assembly shall be given two coats of shop paint, preferably of different colors. *c.* Contact surfaces shall be cleaned, by effective means, before assembly, but not painted. *d.* Machine finished surfaces shall be protected against corrosion by a suitable coating.

**24. ERECTION.**—Frames of all steel-skeleton buildings shall be carried up true and plumb, and temporary bracing shall be introduced wherever necessary to take care of all loads to which the structure may be subjected, including erection equipment, and the operation of same. Such bracing shall be left in place as long as required for safety. *b.* As erection progresses the work shall be securely bolted up to take care of all dead load, wind and erection stresses. *c.* Wherever piles of material, erection equipment or other loads are carried during erection, proper provision shall be made to take care of stresses resulting from same. *d.* No riveting shall be done until the structure has been properly aligned. *e.* Rivets driven in the field shall be heated and driven with the same care as those driven in the shop. *f.* Holes for turned bolts to be inserted in the field shall be reamed in the field as specified in Section 22 *d.* *g.* All field rivets and bolts, also all serious abrasions to the shop coat, shall be spot painted with the material used for the shop coat, or an equivalent, and all mud and other firmly attached and objectionable foreign materials shall be removed, before general field painting. Responsibility for this touch-up and cleaning, as well as for general field painting, shall be allocated in accordance with accepted local practices, and this allocation shall be set forth explicitly in the contract.

**25. INSPECTION.**—*a.* Material and workmanship at all times shall be subject to the inspection of experienced engineers representing the purchaser. All inspection, as far as possible, shall be made at the place of manufacture, and the contractor or manufacturer shall co-operate with the inspector, permitting access for inspection to all places where work is being done. Material or workmanship not conforming to the provisions of this specification may be rejected at any time defects are found during the progress of the work.

**WELDED CONNECTIONS.**—Structural members in steel-frame buildings are welded by flowing fused metal between parts to be welded. The new metal, usually a steel rod 1/8 to 1/4 in. diam. and of the same grade as the connected parts, is deposited as a triangular fillet in a corner between adjoining surfaces. Both electric arc-welding and the oxy-acetylene process are used. As strength of the connection depends on quality of workmanship, only experienced welders should be employed. Connections should be designed to facilitate the work.

The strength of the joint is (allowable load per linear inch of fillet × length of weld, in.). Connections usually are so arranged that shear is the principal stress in the welding material. The connection may be designed either on the basis of shear or by shear and moment. The former method is easier of application and is satisfactory if allowable stresses do not exceed the values of Table 4.

**Table 4.—Allowable Loads per Lineal Inch of Triangular Fillet**

| | | | | | |
|---|---|---|---|---|---|
| Size of Fillet, in. | 1/2 | 7/16 | 3/8 | 5/16 | 1/4 |
| Allowable Load, lb. per lineal in. | 4000 | 3500 | 3000 | 2500 | 2000 |

**Table 5.—Working Stresses in Masonry in Compression**

(From Building Code Recommended by the National Board of Fire Underwriters)

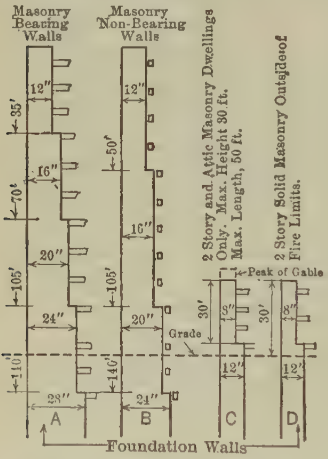
| | Portland Cement Mortar [1] | Natural Cement Mortar [2] | Cement Lime Mortar [3] | Lime Mortar [4] |
|---|---|---|---|---|
| | Stress, lb. per sq. in. | | | |
| Brickwork (see Notes) | 175 | 140 | 140 | 75 |
| Hollow walls of brick | 125 | 100 | 100 | ... |
| Ashlar masonry, dressed granite | 800 | 640 | 640 | 400 |
| " " dressed limestone | 500 | 400 | 400 | 250 |
| " " dressed marble | 500 | 400 | 400 | 250 |
| " " dressed sandstone | 400 | 320 | 320 | 160 |
| Rubble stone | 140 | 100 | 100 | ...... |
| Hollow block,[5] gross area | 80 | 70 | 70 | ...... |
| Solid block,[6] gross area | 125 | 100 | 100 | ...... |
| Concrete [7] (Portland cement) | ...... | 250 | | ...... |
| Concrete [8] (natural cement) | ...... | 150 | | ...... |
| Grout, neat Portland cement in thin layers under bases only | ...... | 1000 | | ...... |

NOTES: 1. 1 part Portland cement, not more than 3 parts sand, proportioned by volume; allowable addition of hydrated lime not over 15% of the cement by volume. 2. Same limitations as for Portland cement mortar, but using natural cement. 3. 1 part cement, 1 part slaked lime or hydrated lime, not more than 6 parts sand, proportioned by volume. 4. 1 part slaked lime or hydrated lime, not more than 4 parts sand, proportioned by volume. 5. A cellular building unit of burnt clay or concrete, whose minimum gross cubic content is 50% greater than the standard size of brick, and whose cellular spaces exceed 25% of the gross cubic content of the unit. 6. A building unit of burnt clay, or of stone, gravel, or cinder concrete, whose minimum gross cubic content is 50% greater than the standard size of brick, and having no cellular spaces exceeding in the aggregate 25% of the gross cubic content of the unit. 7. 1 part Portland cement, not more than 5 parts coarse aggregate, proportioned by volume. 8. Same limitations as for Portland cement, but using natural cement.

## 4. BEARING WALL CONSTRUCTION

For low buildings, generally less than 4 stories high, exterior bearing walls, with an interior frame of timber, structural steel or reinforced concrete supporting the floor construction, are economical. Dormitories, hospitals, club houses and others designed for comparatively light live loads, fall in this class. Architectural design and local conditions control the choice of the structural frame; buildings 4 or 5 stories high may be built economically by either method. Residences and institutional buildings 1 to 3 stories high almost always are of bearing wall construction.

**MINIMUM THICKNESS OF BEARING WALLS** for business and storage buildings are shown in Figs. 5 and 6; for comparison, non-bearing walls also are shown. Minimum thickness of walls over 100 ft. long between cross walls or piers, 16 in. Maximum height of masonry wall between successive floors, or other substantial lateral support (20 × wall thickness), unless reinforced by adequate cross walls, or piers, at intervals not exceeding (20 × wall thickness). Parapets, usually 12 in. thick, are carried 3 ft. above the roof except in residences.



Masonry Bearing Walls
Masonry Non-Bearing Walls

FIG. 5. Minimum Wall Thickness for Residence, Institutional and Public Buildings (*Natl. Board of Fire Underwriters*)

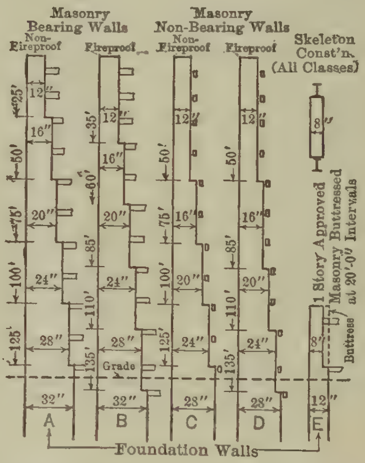

FIG. 6. Minimum Thickness for Business and Storage Buildings (*Natl. Board of Fire Underwriters*)

**WORKING STRESSES.—Natural Stone in Compression,** in lb. per sq. in., may be taken as: Sandstone, 400; marble, 600; limestone, 700; slate, 1000; granite, 1000. **Masonry in Compression.**—See Table 5.

## 5. INDUSTRIAL BUILDINGS

**MULTI-STORY CONSTRUCTION.**—Multi-story buildings for industrial purposes usually are built of reinforced concrete. For structures 3 or more bays wide, with columns located to give approximately square bays of about equal size, the girderless type usually is preferable for superimposed loads of 100 lb. or more per sq. ft. It is more economical than the beam and girder type, except for unusually heavy loads. The ceiling is comparatively flat. Approximately equal column spacing, giving spans of 18 to 22 ft., is economical for average loads from 125 to 300 lb. per sq. ft. Except in warehouses, all exterior wall spaces between columns or piers usually are of glass. Sawtooth roofs may be built if required, but usually are not important in multi-story construction.

Exterior columns usually are of rectangular section; interior columns usually are round, varying from 16 in. to 4 ft. diam., depending on height of building and floor loads. The floor system may be designed with or without drops over the columns; the flared column capital characterizes girderless design and is required by all building ordinances.

Roof surfaces usually are built in the same manner as the floors, if overhead light is not required in the upper story. For drainage, fill is used or the entire area given a slight pitch. Membrane waterproofing often is laid without grade other than that required around parapets and drains.

**SINGLE-STORY CONSTRUCTION.**—Single-story buildings may be of reinforced concrete, but usually are of steel construction. If land is comparatively cheap, the single-story, steel structure has many advantages, *viz.*: no floor space occupied by elevator shafts, stairways and their enclosing walls; no first or operating cost of elevators; less space for columns; better lighting and ventilation; easier supervision of manufacturing processes; a more efficient routing of materials, aiding straight-line production. Also, use of upper floors of a multi-story building is limited by the size and weight of products that can be handled in elevators. The cost of usable floor area in a single-story building often is 25% less per sq. ft. than in a multi-story building of the same gross floor area.

A comparatively recent development (1933) in this field is the controlled conditions plant, without exterior windows; ventilation, air conditioning, and lighting are designed to produce the most desirable working conditions.

**SLOW-BURNING CONSTRUCTION.**—Slow-burning, or mill, construction is seldom used, as reinforced concrete provides greater fire resistance at a relatively small additional cost. Mill construction, originally developed in New England, comprises exterior walls of brick or concrete, with interior framing of heavy timbers carried on wooden posts, supporting floors and roofs of thick planks. Wall openings are supported by masonry arches, or steel or reinforced concrete lintels. Steel lintels over 4 ft. should have 2-in. fireproofing.

**Wooden Columns** should be not less than 8 in. least width; all corners should be rounded or chamfered. Connections between columns and girders should be fire-resistant or protected by materials with a minimum fire-resistance rating of 1 hr.

**Steel or Cast-iron Columns** can be used if protected as required for fire-resistant construction. Stone, cast-iron or steel bases are used under columns resting on floor timbers or masonry foundations.

Beams and girders should be not less than 6 in. least dimension, nor less than 10 in. deep. If built of two or more pieces, sections should be bolted together. Where beams or girders rest on masonry walls, wall plates, boxes of self-releasing type, or suitable hangers should be used. Connections between girders and columns are made by steel or iron straps; girders are fitted closely around columns or butted tightly against them.

**Plank Floors** generally span from girder to girder without cross beams; this design facilitates placing sprinkler pipes and avoids sharp angles to ignite in event of fire. Beams, when used, should rest on top of girders or be supported by steel hangers in which the ends of beams fit closely. If supported on masonry walls, wooden beams and girders should have at least 8 in. of masonry between their ends and the outside face of the wall, and the same thickness between sides of adjacent beams entering a wall from opposite sides. Floors may be tongue-and-groove plank not less than 3 in. thick, with 7/8-in. top flooring laid crosswise or diagonally, or planks not less than 4 in. wide set on edge and spiked together every 18 in. Joints should be broken and located over supports or at the quarter points of the spans. A 1/2-in. space, covered by a molding, between the edges of the floors and walls permits the floor to expand, if wet, without injury to the masonry. All openings or shafts should be protected.

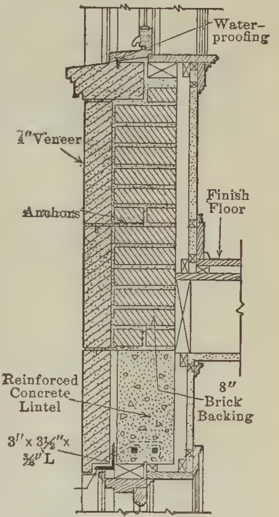

Fig. 7. Stone Veneer with Brick Backing

Roofs are constructed in the same manner as floors, except that plank thickness may be 2 1/2 in. and the roof beams may be 6 in. least dimension. Roof surfaces, covered with membrane waterproofing, usually pitch 1/2 in. per ft.

## 6. WALLS, PIERS AND PARTITIONS

### Stone Work

**MASONRY** of rectangular stones is called **ashlar;** laid in courses with continuous horizontal joints, it is **coursed ashlar;** laid with broken courses and stones of various sizes, it is **broken** or **random ashlar.** **Rubble masonry** is undressed stones of irregular shapes and various sizes. In building construction, moldings, sills, cornice members and ornamental facings of doors and windows are called trimming.

**STONE VENEER,** Fig. 7, usually is 4 in. thick; at least 20% of the face area should be header stones with not less than 4 in. of bond into the backing. Although non-corrodible anchors attach both brick and stone veneer, at least 4 in. of actual bonding, is required to make the veneer part of the legal wall thickness specified by building ordinances.

**MORTAR.**—One part Portland cement, 3 parts sand, 3/20 part hydrated lime, all by volume, generally is used for stone piers, footings, foundations, and heavy masonry below grade. Stone veneer, trim, and exposed work should be set with mortar of non-staining cement, clean, well-graded sand, and hydrated or thoroughly slaked lump lime. Proportions vary for different varieties of stone; an average specification is 1 part non-staining Portland cement, 2 parts sand, and 1/5 part hydrated lime, all by volume. For pointing, the same mixture is used with a fine, white sand. The setting mortar should be applied as parging, 3/4 in. thick, against inner surfaces of all light-colored stone veneers, to prevent staining by the Portland cement used for backing. It is desirable to lay the exterior 4 in. of backing in the non-staining mortar. Black waterproofing compounds, extensively used to protect inside faces of stone veneer, are not a substitute for parging.

**JOINTS** in rubble masonry ordinarily are struck, flush or wiped-out. Ashlar joints usually are raked out 1 in. from the face of the stone and later pointed. Fig. 8 shows various forms of finished joints. All bed joints should be a full bed of mortar, 1/4 in. to 1/2 in. wide. Vertical joints, of the same width, should be thoroughly filled and pointed. Wooden wedges or, preferably, lead buttons give an exact thickness of bed joints.

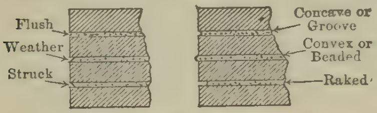

FIG. 8. Types of Brick Joints

**BACKING** for ashlar masonry may be rough stone, common brick, hollow terra cotta or concrete blocks, carried up at the same time as the veneer.

**CLEANING** of marble, limestone, and sandstone should be done with soap and water and bristle brushes, after pointing is finished. Sand blasting, wire brushes, and acids injure the surface.

## Brickwork

Common brick are used for structural walls, piers and for backing stone or terra cotta; well-burned brick are used for surfacing walls. The term *face brick* usually denotes one made for exposed surfaces where a special color, shape, texture or contour is required. Enameled and glazed brick form smooth, impervious surfaces. The Common Brick Mfrs. Assoc. standard size for common brick is 2 1/4 × 3 3/4 × 8 in. Face, enameled, and glazed brick are made in various sizes, approximating these dimensions.

**JOINTS** should be thoroughly filled and each brick laid on a full bed of mortar. For heavy loads, the mortar beds should be smooth, and filled vertical joints are necessary for strength and weather resistance. On purely structural work, mortar joints usually are cut off with a trowel, flush with the wall face, as the work is laid up. On exposed work, joints are finished as for ashlar masonry; the surface of the mortar should be thoroughly compacted to better resist infiltration of rain.

**QUALITY OF BRICK** selected for any particular operation depends on structural or architectural requirements. Well molded units, neither over- nor under-burned give best results. Soft "salmon" brick never should be used. Both highly impervious brick, of low absorption, or highly porous brick having too much absorption, are unsuitable for exterior use. Brick with 5 to 10% absorption will form the most water-tight masonry.

**BONDS** most generally used are Common bond, English and Flemish. Common bond, consisting of 5 or 6 courses of stretchers, followed by a course of headers, is cheapest for ordinary work. In English bond, courses of stretchers and headers alternate. In Flemish bond, headers and stretchers alternate in each course. Face brick may be tied to common brick or hollow tile backing by galvanized iron ties built into the joints, but they then are not part of the legal wall thickness; such veneer should not be considered in computing thickness for stability or bearing.

**MORTAR.**—One part Portland cement, 1 part hydrated lime, 6 parts sand, all by volume, is more desirable for exterior brickwork than mixtures with more cement. Piers or units subject to heavy loads, however, should be laid in mortar of 1 part Portland

**Table 6.—Quantities of Materials Required for 1 Cubic Yard of Mortar**

These quantities allow for loose measurement of aggregates

| Proportions | Cement, bbl. | Sand, cu. yd. | Lime, lb. |
|---|---|---|---|
| 1 Cement: 1 Lime: 6 Sand | 1.25 | 1.1 | 500 |
| 1 Cement: 3 Sand: 10% Lime | 2.50 | 1.1 | 100 |

Mortar required for rubble masonry = 1/3 (total volume of masonry); mortar required for 1000 brick = 17 cu. ft. (3/8-in. joints).

cement, 3 parts sand, 3/20 part hydrated lime, all by volume. Natural cements, also used for brickwork and occasionally for stone masonry, are more plastic than Portland cement; they are mixed 1 part cement, 3 parts, by volume, of sand without lime. Waterproofing compounds added to mortars, particularly those for brick masonry, reduce capillary action. In any case, it is essential to use a well-graded sand and to thoroughly fill the joints; otherwise leaks and efflorescence will result.

**Table 7.—Approximate Quantities of Materials Required for 1 Cubic Yard of Concrete**

These quantities allow for loose measurement of aggregates, and for grouting and waste

| Proportions | Cement, bbl. | Sand, cu. yd. | Crushed Stone, cu. yd. |
|---|---|---|---|
| 1 Cement : 2 Sand : 4 Stone .................. | 1.5 | 0.45 | 0.9 |
| 1 Cement : 1 1/2 Sand : 3 Stone .............. | 2.0 | 0.45 | 0.9 |

## Terra Cotta Tile

**ARCHITECTURAL TERRA COTTA TILE**, used as veneer, are from 12 to 30 in. wide, usually 4 in. thick, and of a height determined by the architectural design. The blocks are hollow and without backs, comprising an outer shell braced by partitions about 6 in. apart. They are attached to the backing by non-corrodible anchors; the joints are finished with cement mortar. Sills, copings, cornices, other architectural members, and veneer, are designed and fitted by the manufacturers for each individual job. Adequate support and thorough drainage are the most essential factors controlling character of the work.

**STRUCTURAL TERRA COTTA TILE** are hollow blocks open at two ends, with interior webs 7/8 in. thick, dividing the units into longitudinal cells. Exterior surfaces are smooth, or scored to give a key for stucco or plaster. Load-bearing tile, for exterior walls and bearing partitions of light buildings, and partition tile for interior non-bearing partitions, are made 12 in. wide and 12 in. high; thickness varies from 3 to 12 in. A variety of other designs, as shoe-tile and backer-tile, are available for backing either stone or brick veneer in load-bearing or curtain-wall construction.

Besides the various varieties of floor tile, fireproofing tile and book-tile (see Floor and Roof construction, p. 17–24), **terra cotta furring tile** is used to line inside surfaces of exterior masonry walls. These usually are 3 or 4 in. thick, scored by the manufacturers, and split to 1 1/2 or 2 in. thick. When placed against an exterior wall, the voids between the ribs provide a dead air space, forming insulation against cold or dampness. The ribs are set vertically in mortar, and held in place by metal ties or 10d. wire nails bent down over the tops of the tile. Partition blocks, 3 in. thick, tied to the wall by metal anchors, also are used for furring.

**LOAD-BEARING TILE** are used for exterior walls of residences, small stores and garages; most building codes prohibit them in walls over 40 ft. high. The cells are placed vertically, and special tile are used for jambs, sills, and corners. Mortar is the same as for brick masonry.

**BACKER TILE** of various designs is used for veneered bearing walls and for structural portions of curtain walls in skeleton construction. They weigh less than common brick, lay more quickly, and furnish better insulation, thereby eliminating furring.

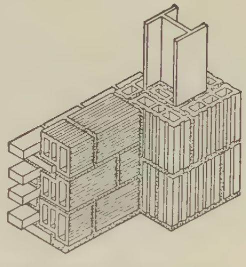

Fig. 9. Brick Veneer with Tile Backing. Note Column Fireproofing

**PARTITION TILE** are lighter and generally more porous than load-bearing tile, and are used for interior partitions in fire-resistant buildings. A 6- or 8-in. tile usually is required for stair or elevator enclosures; 4-in. tile for corridors; 3-in. tile for room partitions. Salt-glazed and enameled surfaces also are made, as well as plain and scored surfaces.

## Concrete Blocks and Cast Stone

**HOLLOW CONCRETE BLOCKS** are made both with sand and cinder aggregates. The latter is more widely used, as units weigh less, are better insulators, are more nailable, and make a better bond when used as a base for exterior stucco.

Concrete blocks are made in various sizes; a typical unit is 8 × 8 × 16 in. When used for exterior walls of light buildings, they usually are stuccoed on the exterior; when used for other than garages or machine shops, interior surfaces should be furred. Cinder blocks are used for backing panel wall construction and for interior partitions. The shape is adapted to each particular use. As all cement products shrink during hardening, they should be at least 28 days old before use. Both cement-sand and cement-cinder units are laid in the same mortar as brick masonry.

**CAST STONE** is used architecturally as a cheaper substitute for natural stones and to produce color and texture effects impossible with natural products. It usually is composed of either white cement or standard Portland cement, mixed with appropriate aggregate to the consistency of thin concrete, and poured into sand, wood, metal, plaster or glue molds. Dry pigments give the desired color.

Rectangular blocks, for veneer of buildings and molded units of simpler shape, are cast in sand molds, using strips of wood or metal embedded in the sand to form curved surfaces. The more complicated shapes are cast in plaster molds; glue, or a similar elastic composition, is required for undercut work. If the surface color or texture requires a costly mixture, the body of the unit is made of cheaper materials, otherwise the entire member is of the same composition. After hardening and curing, the surface film of cement is removed by fine water spray or acids. To avoid surface cracking or crazing and the shrinkage of cast stone products after placement, only the best materials should be used; the mixture and surface treatment should insure proper weathering; and the units must be thoroughly cured before use.

### Gypsum Tile

Besides the use of gypsum tile in floors and roofs, gypsum is used for partitions, furring and fireproofing. The tile are either solid or hollow; the latter have circular cell spaces.

**PARTITION TILE** generally are made 12 in. high, 30 in. long and 2 to 6 in. thick. Gypsum tile are lighter than terra cotta, are sawed easily, and offer better nailability.

**FURRING TILE** are made 3 and 4 in. thick. They are scored by the makers and split to 1 1/2 or 2 in. thick. They are set the same as terra cotta furring.

**FIREPROOFING TILE** are made in shapes to fit the lower flanges of I-beams. Both soffit and angle tile are made for fireproofing; solid and hollow partition tile are used to insulate structural steel members.

**MORTAR** for all gypsum units should be 1 part gypsum plaster, 2 or 3 parts, by weight, of clean sand. Portland cement mortar should not be used with gypsum blocks.

**GYPSUM PRODUCTS** should not be used where moisture is present. When dry, they are excellent for non-bearing partitions, but have not the structural strength of terra cotta.

### Metal Lath and Plaster Board Partitions

**FIRE-RESISTANT PARTITIONS** may be built by supporting metal lath on a light, rolled-steel framework and applying two coats of Portland cement mortar to each side. This design is useful for enclosing small areas, as office spaces, in certain types of industrial buildings. The supports are bolted to floor and ceiling; total thickness approximates 2 in.; 2-in. channels are used for door frames.

**PLASTER BOARDS,** composed chiefly of gypsum, and many types of fiber boards, may be used as a base for gypsum plaster; in some cases no surface treatment is given. Most of these are fire-resistant, but the actual fire rating allowed by the Underwriters should be checked for each particular construction before use.

## 7. FLOORS

About 20 systems of fire-resistant floor construction are in use. Each has its advantages and limitations, and the system best adapted to the particular building should be chosen. Certain types are suitable only for reinforced-concrete framing; others are adapted only to structural steel. The type of occupancy being known, the floor loads may be determined from the local building ordinances. Floor loads will dictate the floor construction, some systems being adapted to light and others to heavy loads. Many designs are suitable only for short-span construction; some are one-way systems only; others are either one- or two-way systems; these features control their adaptability to the architectural plan. Supplementing purely structural features, final choice between acceptable designs usually will depend on economic conditions.

### Types of Fire-resistant Floor Construction

In addition to the various types of reinforced concrete, hollow tile, gypsum and concrete block systems of floors (see below), the metal pan system generally is used in both steel-frame and reinforced-concrete buildings. The metal dome system has been used with reinforced concrete framing. Metal lumber and open-web steel joists are used in buildings for light occupancy; steel plate designs in certain types of industrial work. They are not adapted to a reinforced concrete frame. Concretes with light-weight aggregates, as Haydite, and light-weight concretes, as Aerocrete and Porete, and gypsum, are precast into slabs supported by structural steel in short span construction; slabs are poured in place on steel-frame buildings.

**THE GIRDERLESS REINFORCED CONCRETE FLOOR** is particularly adapted to multi-story industrial work. For design procedure, see Eshbach, Handbook of Engineering Fundamentals, section 5, forming Vol. 1 of this series.

**THE BEAM-AND-SLAB SYSTEM** usually costs more than girderless designs. It is used for comparatively heavy live loads where an economical column spacing is impracticable, or where flared column heads are objectionable. This system may be used with reinforced concrete frames, bearing wall construction, or structural steel framing.

Floor systems in steel-frame, multi-story buildings are: 1. Short-span construction, including cinder concrete arches and flat or segmental terra cotta arches; 2. Long-span construction.

**CINDER CONCRETE ARCHES** usually span between I-beams framed into girders at $^1/_3$ points of girder spans. Usual floor thickness is 4 in. on clear spans up to 8 ft.; corresponding roof thickness is 3 $^1/_2$ in. Concrete mixture by volume is 1 part Portland cement, 2 parts sand, 5 parts clean, well burned steam-boiler cinders. Wire fabric reinforcement is used, based on empirical data. See Table 8. According to the New York City ordinance, $L \leqq \{(h \times A)/S^2\} \times c$, where $L$ = gross load on floor, lb. per sq. ft.; $h$ = depth of reinforcement below top of slab, in.; $A$ = cross-sectional area of tension steel, sq. in. per ft. width; $S$ = span, ft.; $c$ = constant whose values are as follows for cinder concrete: 14,000 for reinforcement not continuous over supports; 18,000 for reinforcement of rods or other shapes securely hooked over or attached to supports; 26,000 for steel fabric reinforcement continuous over supports; for stone concrete the corresponding values of $c$ are 16,000, 20,000 and 30,000 respectively. If permitted by building ordinances, cinder-arch construction is economical for live loads up to 75 lb. per sq. ft.; it is used only between structural steel beams.

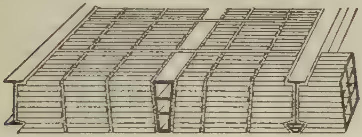

Fig. 10. Typical Section End Construction Hollow Tile Flat Floor Arch. (*Natl. Fireproofing Co.*)

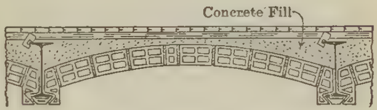

Fig. 11. Typical Section Segmental Hollow Tile Floor Arch (*Natl. Fireproofing Co.*)

**HOLLOW TILE ARCHES** usually are of shorter span than cinder concrete arches. They are supported by I-beams framed into girders at $^1/_3$ or $^1/_4$ points of girder spans. This construction is excellent for hotels and office buildings, permits alteration more easily than competing long-span systems, but first cost is higher. Flat hollow tile arches use tile from 6 to 16 in. deep, depending on load and span. Minimum depth is 1 $^1/_2$ in. per foot of clear span, but never less than 6 in. Lower flanges of supporting members are

**Table 8.—Area of Steel Wire Reinforcement for 4-in. Cinder Concrete Arches**

Load uniformly distributed. Spans limited to 8 ft., 0 in. Concrete mix: 1 cement : 2 sand: 5 cinders, by volume. Reinforcement, steel fabric, continuous over supports, placed 1 in. from bottom of slab. Weight of 4-in. slab = 36 lb. per sq. ft. Values are based on empirical data approved by New York City Building Dept. for short-span construction.

fireproofed by special soffit blocks. Segmental hollow tile arches, and occasionally brick arches, are used for heavy loads; both systems have been largely superseded by more economical designs. Segmental arches require tie rods just below centers of adjacent beams, and in line across a floor area. For hollow tile arches, in interior bays, sizes and spacings are as follows.

| | | | |
|---|---|---|---|
| Span, ft | 6 or less | 6–7 | 7–9 |
| Diam. of rod, in. | $^3/_4$ | $^7/_8$ | $^7/_8$ |
| Center distance of rods, ft | 5 | 5 | 4 |

**LONG-SPAN CONSTRUCTION,** comprising essentially reinforced concrete joists separated by terra cotta, concrete or gypsum blocks or by voids formed by wood or metal cores, may be used with bearing walls, reinforced concrete or structural steel framing. Fillers usually are 12 to 20 in. wide; joists 4 to 5 in., spaced 16 to 25 in. centers. A continuous slab, or topping, 2 to 3 in. thick forms the floor surface. These systems are used for buildings other than industrial, carrying live loads of 40 to 125 lb. per sq. ft. They support the floor loads of an entire bay, and intermediate beams are unnecessary. Dead load is also much less than with solid concrete slabs.

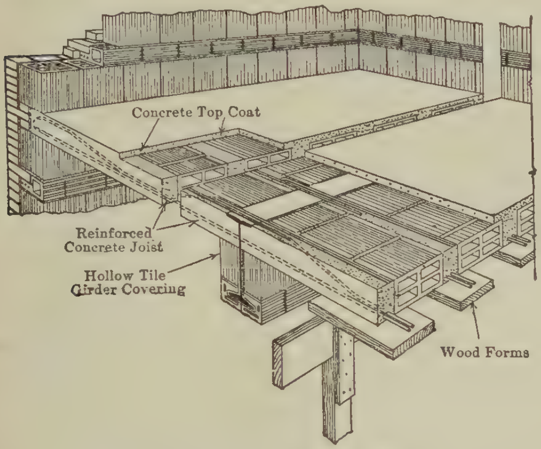

FIG. 12. Long-span Hollow Tile Construction (*Natl. Fireproofing Co.)*

The use of filler block (terra cotta, concrete or gypsum) gives a more substantial floor than when joists are separated by voids. Block systems are heavier and more costly than metal or wooden pan designs, but permit plaster to be applied directly to soffits of the blocks; otherwise metal lath must be used for a flat ceiling across soffits of the ribs.

Both terra cotta and concrete blocks are used as fillers in two-way systems. Such designs, comprising two sets of reinforced concrete joists, parallel to the sides of the panels. are economical for square or nearly square rectangular bays, *i.e.*—(longer side ÷ shorter side $\overset{=}{<}$ 1.25). Metal pans also are made in domes adapted to two-way design. They are used only in reinforced concrete buildings.

**PRESSED STEEL SECTIONS** (metal lumber) are used in buildings for light occupancy, where great fire resistance is not required. These sections, normally 8 to 16 in. deep, supported by steel girders spanning between columns, are used on 12 to 30 in. centers to carry a thin concrete floor slab, usually 2 $^1/_2$ in. thick, poured over a closely spaced metal lath which acts both as forms and reinforcement.

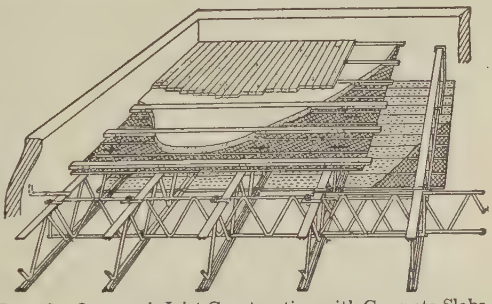

FIG. 13. Open-web Joist Construction with Concrete Slabs, Sleepers and Wood Flooring (*Concrete Steel Co.)*

**OPEN-WEB STEEL JOISTS** have largely superseded pressed steel sections. They are used in the same manner and are satisfactory for short, medium and comparatively long spans for light live loads, and where the plastered lath used as insulation for the soffits of the joists furnishes sufficient fire resistance.

**Open-web Steel Joists and Structural Aerocrete Construction,** topped with stone concrete is economical for light and medium live loads on spans up to 25 ft. It can be quickly

(*Continued on page* 17–32)

### Table 11.—Core Depth and Steel Area for Long-span Metal Core Construction

Cores 25 in. base; 5 in. reinforced concrete joists, 30 in. on centers; 2 1/2-in. concrete top. Compressive unit stress in extreme fibers of concrete = $f_c$ = 700 lb. per sq. in. Tensile unit stress in steel = $f_s$ = 18,000 lb. per sq. in. For safe loads using 16,000 lb. per sq. in. in steel, and 650 lb. per sq. in. in concrete, multiply loads given by 0.89, and subtract from the result the factors shown in each section of the table. Loads to left of first zigzag line produce shears under 40 lb. per sq. in. Loads between zigzag lines require tapered-end cores for shear and for compression over continuous supports. Loads to right of second zigzag line develop higher stresses and should be investigated. Data were supplied by Berger Mfg. Co.

erected, gives smooth ceilings and has low dead load; structural aerocrete weighs 60 lb. per cu. ft. Spans of 22 ft. will carry a 60-lb. superimposed load on a total thickness of 10 $^1/_2$ in., including 1-in. fireproofing below, and 1 $^1/_2$ in. above, joists. Topping would be of 1 : 2 : 4 stone concrete, 2 $^1/_2$ in. thick, with joists spaced 4 ft. 0 in. with adequate bridging. Near the upper surface $^1/_4$-in. rounds, 1 ft. 6 in. centers, are run across the joists and a continuous sheet of welded wire fabric reinforces the aerocrete slab between joists.

**STEEL PLATE FLOOR CONSTRUCTION.**—Comparatively shallow I-beams spanning between girders and carrying sections of steel plate welded together to form the floor, are used in industrial buildings. Such floors are very shallow, as the I-beams are stiffened by the plates welded to the upper flanges; when properly insulated, they are economical for certain types of industrial work.

**CELLULAR STEEL FLOOR CONSTRUCTION,** comprising thin steel sheets formed and welded to produce a hollow structural unit 12 in. or 24 in. wide, can be used on short and medium spans to make a light and inexpensive floor which may receive any desired surface treatment. This system offers particular advantages for running conduit within the floor thickness and can be used economically with a structural steel frame where fireproofing requirements can be met.

**FLOOR FILLING** in fire-resistant buildings usually is cinder compacted by tamping and often mixed with Portland cement (1 part cement, 8 parts cinder by volume). The depth of fill is 3 or 4 in., providing space for pipes and conduits. With open-web steel joists or hung ceilings, fill usually is unnecessary except for the embedment of sleepers for finished wood floors, or for insulation.

Small-sized conduit may be placed in structural members of concrete ribbed floors; with solid reinforced concrete slabs the conduit is embedded in the slab. For most commercial, institutional and residence construction floor fills usually are required.

**Table 13.—Tile Depth and Steel Area for Long-span Hollow Tile Construction**

Blocks 12 × 12 in.; 4-in. reinforced concrete joists; 2-in. concrete top. Compressive unit stress in extreme fibers of concrete = $f_c$ = 650 lb. per sq. in. Tensile unit stress in steel = $f_s$ = 16,000 lb. per sq. in. Shear limited to 60 lb. per sq. in. $T$ = tile thickness, in.; $S$ = steel area in each joist, sq. in.; $^3/_4$ in. concrete protection below reinforcement.

WEIGHT OF LONG-SPAN HOLLOW TILE CONSTRUCTION PER SQ. FT.

Blocks 12 × 12 in.; 4-in. reinforced concrete joists; 2-in. concrete top. Data from National Fireproofing Co.

| Tile, in. | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 12 | 15 |
|---|---|---|---|---|---|---|---|---|---|---|
| Weight, lb. | 45 | 50 | 55 | 60 | 65 | 70 | 75 | 80 | 90 | 105 |

* For safe superimposed load, deduct from total load shown in table, the weight of the construction.

† If moment $WL/12$ is used, investigate design for shear.

## Table 14.—Total Safe Loads, Uniformly Distributed, Lb. per Sq. Ft. for Open-web Steel Joists *

This table is based on the standard specification for steel joists of the Steel Joist Institute. Spacing limited to 24 in. in floors and 30 in. in roofs, except where roofing consists only of wood, or sheet metal, the spacing may be increased to 7 ft. All joists must have adequate bridging, bearing and anchorage.

| Span, ft. | Spacing Center to Center of Joists, in. | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | 16 | 17 | 18 | 19 | 20 | 21 | 22 | 23 | 24 | 25 | 26 | 28 | 30 |

* For safe superimposed load deduct from total load shown in table the weight of the joists as follows: 8-in., 3.42 lb.; 10-in., 4.00 lb.; 12-in., 5.00 lb.; 14-in., 6.92 lb.; 16-in., 8.30 lb. Weights are per lineal feet of joist. Data from Truscon Steel Co.

### Table 15.—Safe Loads, Uniformly Distributed, Pounds per Square Foot, for Floor Joists

$f$ = extreme fiber stress, lb. per sq. in., $v$ = horizontal shear, lb. per sq. in.

NOTE.—Loads shown in tables are live and dead loads computed for common grade on exact sizes. Loads to right of heavy lines are safe loads but will cause deflections greater than 1/360 span. Values in beam table are for beams or girders 1 in. thick and laterally supported; multiply by the actual, *not* nominal, width of member.

| Size of Joist, in. (nominal) | Spacing, in., Center to Center | Douglas Fir, Coast Region $f = 1200$, $v = 72$ | | | | | | | | Southern Yellow Pine $f = 1200$, $v = 88$ | | | | | | | | Douglas Fir, Rocky Mountain Region, Red, White and Sitka Spruce $f = 880$, $v = 68$ | | | | | | | | Redwood $f = 960$, $v = 56$ | | | | | | | |

**PRECAST SLABS,** supported by steel framing, form good structural surfaces and may be used for floors carrying light loads. Commercial slabs, 2 to 3 in. thick, of light weight concretes or gypsum, reinforced with small rods, span 2 to 4 ft.

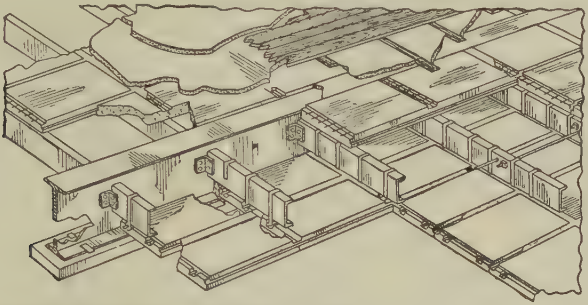

Fig. 14. Gypsteel Precast Floor Construction Showing Steel Channels and Supporting Girders

## Wood Joist Floors

For other than fire-resistant buildings, wood is the prevailing material used for floors. Lally columns and structural steel girders have replaced timber posts and wood girders. Wood joists 2 in. thick × 10 or 12 in. deep are used; on long spans a 3 × 14-in. joist may be required. Joists are usually set 16-in. centers with lines of $^7/_8 \times 3$-in. bridging spaced not over 8 ft. apart. For finished floors an underflooring of $^7/_8 \times 6$-in. tongue-and-groove

roofers is laid diagonally over the joists and nailed with at least two 8d. wire nails in each board. The diagonal sub-floor strengthens wood-frame buildings, and the finished floor may be laid in any direction. Waterproofing paper should be placed between the two floors in basements, and ordinary building paper in the upper stories.

**FLOORS LAID ON THE GROUND.**—To prevent dampness, floors on the ground must be drained; to prevent settlement the surface must be uniformly firm and well compacted. On dry, well-drained soils, 6 in. of cinder, thoroughly tamped and evenly surfaced suffice. Stone-concrete (1 part Portland cement, 3 parts sand, 5 parts crushed stone or gravel, by volume), 4 in. thick is satisfactory for cellar floors with granolithic finish. For damp sub-soil, 12 in. of broken stone should be under the cinder fill; if water is present, sub-drainage is necessary; even if there is no hydrostatic head, a dampproofing course of membrane waterproofing, and a layer of hollow tile, or both, may be used if finished floor is wood, or if the rooms are used for living quarters. If actual hydrostatic head exists at basement level, adequate waterproofing is required. See p. 17–44.

## Floor Finishes

In factories and warehouses, cement floor finishes are common; wood blocks are preferable for heavy traffic. Cement floors are used in public, commercial and institutional buildings, with clay tile, cork, rubber tile and various composition floorings in baths, lobbies, offices, etc. Wood flooring, excepting wood block floors, is used in residences, apartments, club-houses, assembly halls and gymnasiums.

**CEMENT FLOORS** may be laid integrally with the concrete base, or bonded to the base later, or laid on cinder fill. The integral floor is cheapest if conditions permit a monolithic finish as the floor is laid. A thin layer of dry mortar (1 part cement, 1 $^1/_2$ parts sand, by volume) is spread on the slab within $^1/_2$ hour after laying the latter, and finished with a steel trowel. The surface may be left exposed or covered with linoleum. The amount of material depends on the smoothness of the slab; a fair estimate is 2 $^1/_2$ bbl. Portland cement and 15 cu. ft. well-graded, screened sand per 1000 sq. ft. of floor.

Bonded cement floors are of cement mortar (1 part cement, 1 part sand, 1 part finely crushed stone, called grits), laid about 1 $^1/_4$ in. thick. For each 1000 sq. ft. allow 15 bbl. Portland cement, 2.25 cu. yd. screened sand and 2.25 cu. yd. grits. The slab is roughened, cleaned, thoroughly wet, coated with a grout of cement and water, immediately before laying mortar. The latter, mixed to a stiff consistency, is tamped and finished with a steel trowel. Space for pipes is provided by laying the floor finish on a moistened and compacted bed of steam cinder covering the pipes, the surface being reinforced with wire fabric. All cement finishes should be protected by paper or burlap as soon as the surface has hardened, and covered with soft wood shavings, earth or sand kept wet for 10 days. Proprietary compounds, as hardeners, give a hard, dustless surface.

**TERRAZZO FLOORS** comprise a 1-in. surface layer of cement and graded aggregates, on a 2-in. layer of stone concrete on slab or floor fill. The surface is finished by polishing machines which expose the aggregate. To prevent cracking, brass strips $^1/_8$ in. wide, extending through the entire thickness of concrete and finish, divide the floor into panels.

**CLAY TILE,** vitreous and semi-vitreous, usually are laid on a $^1/_2$-in. mortar setting bed over a 2-in. bed of stone concrete or 2 $^1/_2$ in. of cinder concrete on the slab. A 3-in. minimum should be used over earth or fill. The setting bed should be reinforced with wire fabric to prevent cracking. The ceramic mosaic designs of small sizes of unglazed tile are used for the floors of bathrooms and toilets. Ceramic tile are arranged in various patterns, glued on sheets of paper which are soaked off after placement.

**CORK TILE,** composed of cork shavings pressed into squares and rectangles, are made in various shades of brown, from $^5/_{16}$ to $^9/_{16}$ in. thick. They are laid in paste over cement floors, giving a resilient, noiseless finish, but are too expensive for ordinary work.

**LINOLEUM** is finely ground cork pressed into wide strips. It ranges from $^1/_8$ to $^1/_4$ in. thick. The $^1/_4$-in. thickness is battleship linoleum. It is pasted to cement floors without lining, but on wooden floors a felt lining is used.

**RUBBER TILE FLOORING,** laid directly on cement floors, or with a lining on wood floors, makes a resilient, waterproof surface. Individual units are square or rectangular, from $^3/_{16}$ to $^1/_2$ in. thick.

**COMPOSITION FLOORING** usually is magnesite or asphalt, laid in a plastic state. Magnesite flooring usually is laid in two coats of $^1/_2$ in. total thickness, on wood or concrete base. It comes in a variety of colors, is resilient and waterproof. Asphalt compositions usually contain asbestos fiber mixed with mineral pigments. They are laid as tile or in the plastic state. Thickness for heavy foot traffic is $^1/_4$ to $^3/_4$ in.; for trucking, 1 to 2 in. Asphalt often is mixed with marble chips or crushed rock, formed in blocks, and ground down to obtain the effect of terrazzo.

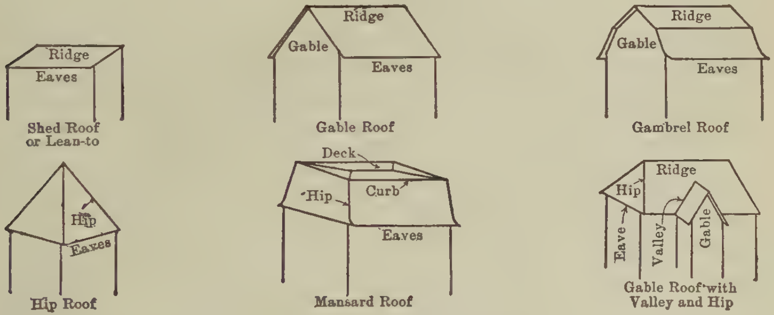
**WOOD BLOCKS** of yellow pine or redwood, with grain vertical, are used to resist heavy traffic in warehouses and factories. Laid on a concrete base, in pitch or asphalt binder, they form a lasting surface. Thickness usually is 2 to 4 in.

**STRIP FLOORING** of oak, yellow pine or maple is used for residences and institutions. A $^{7}/_{8} \times 6$ in. tongue-and-groove diagonal underflooring first is laid on the wood joists, with building paper between it and the finish floor; in basements waterproof paper should be used. With fire-resistant floors the underflooring is nailed to sleepers embedded about 20 in. apart in cinder concrete. Occasionally nailing strips are embedded in the upper surface of the slab, or 2 in. of Nailcrete or Nailcote over the floor fill provides nailing for the underflooring. Strip floorings usually are $^{13}/_{16}$ or $^{25}/_{32}$ in. thick; for heavy traffic the thickness may be up to 2 $^{5}/_{8}$ in. Face widths vary from 1 $^{1}/_{2}$ to 3 $^{1}/_{4}$ in.; both sides and ends are tongue-and-groove, and the backs slightly hollowed to prevent warping.

## 8. ROOFS

### Method of Supporting Roofs

**FLAT ROOFS** for multi-story reinforced concrete buildings, are designed the same as floors; the live load is less and the structural members correspondingly lighter. The structural slab is pitched $^{1}/_{4}$ in. per foot for drainage, or cinder filling may be used. A 5-ply built-up membrane, flashed into parapets and penthouses, generally is used as surfacing. If shallow pools of water on the wearing surface are not objectionable, roofs may be laid absolutely flat.



Shed Roof or Lean-to

Gable Roof

Gambrel Roof

Hip Roof

Mansard Roof

Gable Roof with Valley and Hip

Fig. 15. Types of Roofs

**PITCHED ROOFS** may be framed with concrete, steel or wood. Concrete is not economical unless the structural members are elements of a rigid frame; such construction is not used generally in the U. S., but in Germany and France, it is used in auditorium and hangar construction.

Steel trusses are used for pitched roofs of both wall-bearing and steel-frame buildings. Wood trusses, particularly the bow string type, are economical for garages and some

FIG. 17. Typical Gable Roof Design

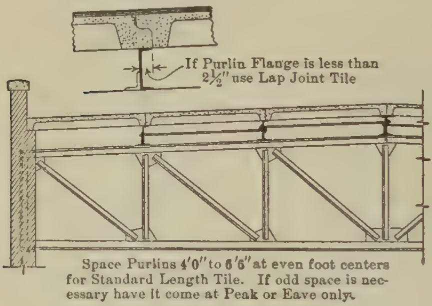
industrial buildings. Lamella designs, both steel and wood, are used for auditoriums and industrial plants. Steel arches may be economical in one-story structures.

A complete roof system, supported by trusses, consists of roof deck, rafters, purlins and trusses. A bay is the roof area between two trusses. Purlins are horizontal beams between trusses. Roofs may be laid directly on purlins, or on sub-purlins parallel to the trusses. Roof trusses comprise inclined or horizontal top chords, horizontal or cambered lower chords, and web systems. Panel points are joints where web members intersect chords; the distance between them is the panel length.

The **height** of a truss is the vertical distance from peak to a horizontal line passing through both supports. **Pitch** is the ratio of rise to span length. **Slope** is the ratio of rise to $1/2$ span. A truss of 10 ft. rise and 40 ft. span has a pitch of $1/4$, a slope of $1/2$ or of 6 in 12. If architectural design does not control the slope, a pitch of $1/4$ generally is economical.

## Loads on Roofs

**THE DEAD LOAD** on a roof truss comprises the weight of the truss, purlins, rafters, roof deck and covering, and any suspended ceilings or floors. The approximate weight of roof trusses up to 75 ft. span, under normal conditions, is about 10% of the load to be carried. When the truss is designed, actual weight should be computed and compared with assumed weight.



If Purlin Flange is less than 2½" use Lap Joint Tile
Space Purlins 4'0" to 6'6" at even foot centers for Standard Length Tile. If odd space is necessary have it come at Peak or Eave only.

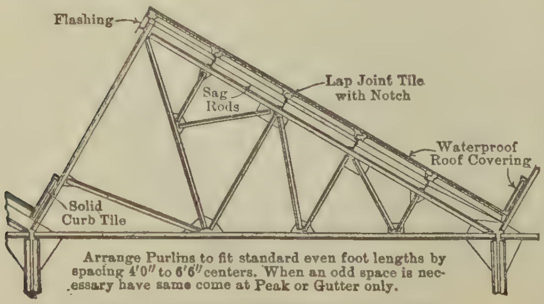
FIG. 18. Typical Flat Roof Design

**THE LIVE LOAD** is the sum of probable snow and wind loads. The former depends on geographical location, roof slope and character of roof covering. Table 17 gives snow loads for various locations and roof slopes.

**Wind Pressure** on an inclined roof is that acting in a direction normal to the surface. Duchemin's formula, the most widely used, is

$$P_n = P\{2 \sin A/(1 + \sin^2 A)\},$$

where $P$ = unit pressure, lb. per sq. ft.; $A$ = angle of roof surface to the horizontal. Table 18 gives values of $P_n$ when $P = 20$ and $P = 30$. The value of the wind load carried to each panel point of the truss is $(P_n \times L \times d)$, where $L$ = panel length and $d$ = distance between trusses, ft. Maximum wind pressure stresses are assumed by considering the wind acting in one direction on one side of the roof and then in the reverse direction on the opposite side.



Flashing
Sag Rods
Lap Joint Tile with Notch
Waterproof Roof Covering
Solid Curb Tile
Arrange Purlins to fit standard even foot lengths by spacing 4'0" to 6'6" centers. When an odd space is necessary have same come at Peak or Gutter only.

FIG. 19. Typical Sawtooth Roof Design

**Combined Roof Loads** include both snow and wind loads. They are taken as a uniform vertical load acting over the entire roof surface. Values are given in Table 19; the total uniform vertical load is the tabular

value plus dead load. The panel load is $A \times (D + C)$, where $A$ = area of panel, sq. ft., and $D$ and $C$ = dead load and combined load respectively, lb. per sq. ft. The estimated weight of the truss is distributed among the panel points, and the weight of the purlins added.

**PURLINS** are placed at panel points on top chords of roof trusses; sometimes one or more are placed between panel points. Each purlin supports a roof area of (panel length, *i.e.*, distance between purlins, × length of bay, *i.e.*, distance between trusses). With purlins between panel points, the top chord must be designed for bending combined with direct stress. The vertical load on a purlin may be resolved into components normal and parallel to the roof slope. If the roof deck gives lateral support, the parallel component may be assumed as carried by the deck; if the deck lacks rigidity for lateral support, $^5/_8$-in. or $^3/_4$-in. tie rods are run from purlin nearest the heel on one side of the truss, over the ridge, and down the other side. These should be placed at the center of $^1/_3$ points of purlin spans. Tie rods seldom are necessary on roofs of slope less than $^1/_4$. The component perpendicular to the roof is found graphically, and the purlin designed as a simple beam. See p. 17–47.

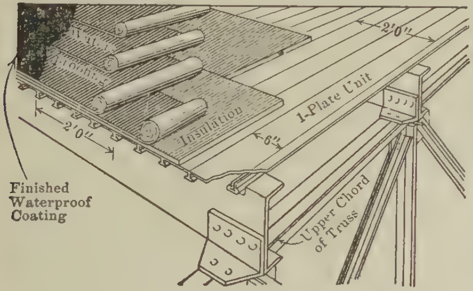

Fig. 20. Typical Steel Deck Construction (*Truscon Steel Co.*)

## Roof Decks

**STEEL ROOF DECKS.**—One type of deck uses hollow ribbed units over standard steel rafters and purlins. Its weight, including insulation and waterproofing, approximates 5 lb. per sq. ft. Sheets are end-lapped and attached to purlins by clips. For additional rigidity, arc-welding replaces clips.

Another type is No. 16 or 20 gage galvanized steel sheet with interlocking ribs 1 $^1/_2$ in. deep, spaced 6 in. apart, in lengths up to 12 ft. No. 18 gage is used on spans up to 8 ft.; the weight is 3 $^1/_4$ lb. per sq. ft. Steel roof decks may be covered with composition roofing or prepared for slag, slate or tile.

**GALVANIZED STEEL SHEATHING,** pressed into channels, is economical on a purlin spacing of about 4 ft. When rolled from No. 24 gage steel, the sections are 18 in. wide. This construction is suitable for flat roofs, when covered with insulation and membrane roofing.

**SLABS CAST IN PLACE,** supported directly by purlins have been used on better classes of work, but have given way to precast units.

**PRECAST SLABS** of light weight concrete, gypsum or similar materials are used for roof decks on fire-resistant buildings. The units are small, easily handled, and of sufficient structural strength to span between sub-purlins. They can be adapted to any type of roof surface.

Porete and Aerocrete are patented materials. Porete comes in slabs about 1 1/4 in. thick, 24 in. wide, 32 in. long. They are placed between T-shape sub-purlins, spaced about 2 ft. 9 in. centers. Larger units, up to 3 in. thick are suitable for a 6-ft. span. Slabs are reinforced with woven galvanized netting and fastened to the purlins by clips. Porete is highly porous, and is an excellent insulator. On flat or slightly sloped roofs, membrane waterproofing is laid on a 1/4-in. layer of cement and sand mixed with a small amount of nailing compound. For slate or tile the layer is 1/2 in. thick.

Porete slabs cast in channels may be used on a 6-ft. span; this assembly weighs 12 lb. per sq. ft. A combination of steel roof deck and Porete, comprising a ribbed steel unit 18 in. wide, ribs 6 in. apart, and a layer of light-weight nailing concrete, can be used on spans up to 10 ft. It is adapted to both flat and pitched roofs with any type of surface.

3 in. thick. Structural Aerocrete, cast 3 to 4 in. thick may be used on spans up to 8 ft. It can be made to weigh 30 to 80 lb. per cu. ft.; strength increases with the weight.

Precast gypsum units on bulb T-sections make an excellent surface under tile or slate for short-span roofs. The Gypsteel system comes in several designs; the long-span suspension type is suitable for spans up to 7 ft. between purlins. The short-span system comprises 30-in. slabs resting on bottom flanges of sub-purlins. Another system comprises sheet rock forms on sub-purlins, spaced approximately 32 in. centers, over which gypsum stucco, containing 12 $^1/_2$% of wood fiber, by weight, is poured. Reinforcement is galvanized fabric. Weight is approximately 55 lb. per cu. ft. This design can be used for roofs pitched up to 30 deg.

**PRECAST SLABS** (Haydite) of light-weight aggregates made from burnt slag and reinforced with wire mesh, weigh about 10 lb. per sq. ft., when designed for spans up to 6 ft. For slate, tile or sheet metal, $^1/_4$ in. of nailing material is cast integrally over the top surface. Including surfacing, the slabs weigh 18 lb. per sq. ft. when adapted to 5 ft. purlin spacing.

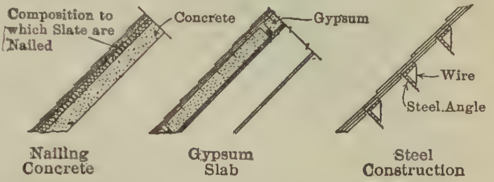

Fig. 22. Methods of Applying Slate over Various Types of Construction (*Natl. Slate Assoc.*)

For flat or steeply inclined roofs, gypsum slabs, 2 × 15 in., form economical decks for spans up to 7 ft. They weigh 11 lb. per sq. ft., are fire-resistant and good insulators.

## Roof Surfacing Materials

**CONCRETE TILE** is used for both flat and pitched roofs, particularly on industrial work; standard size of interlocking type is 24 × 52 in., 1 $^1/_8$ in. thick. Slabs hook over steel channel purlins, overlap and interlock, and are sealed with plastic cement on four sides. No surfacing is required. Purlins are spaced 4 ft. centers. Tile are made with Haydite aggregate and permanent colors on outer surfaces.

**CLAY TILE, SLATE AND ASBETOS SHINGLES** may be laid over any of the above roof decks, if nailing is provided. With stone or cinder concrete without other surfacing, 1 × 2 in. beveled wood strips are embedded in the slabs, over which a 30-lb. roofing felt is laid. A nailable surfacing is preferable to wood strips. Non-corrodible nails should be used with surfacing materials.

The length of slate usually is taken as (2 × exposure + head lap); on roofs of normal slope, head lap = 3 in. On steep roofs, as Mansard, 2-in. head lap is sufficient. Slopes less than 4 in. per ft. are treated as flat decks.

**SLATE.**—A formula derived from the recommendations of the National Slate Assoc. for estimating number of squares of slate required for a building is

$$S = K\{L \times a(R + 0.5) - {}^1/_2 M + D + H\} \div 100$$

where $S$ = squares of slate; $L$ = length of roof, ft.; $R$ = length of rafters, ft.; $M$ = (area of chimneys $c$ + area of dormers $d$), sq. ft.; if $(c + d) < 20$, $M = 0$; if $(c + d) > 80$, $M = (c + d) - 20$; $D$ = area of dormer roofs, sides of slated dormers, slated saddles and other slate surfaces, sq. ft.; $H$ = total length of hips and valleys; $a$ = constant = 1 for single slopes, and 2 for double slope roofs. $K$ = constant ranging from 1.02 to 1.15, depending on the number of intersections of other roofs, dormers, etc.

**TILE SLABS, QUARRY TILE** vary from 6 × 6 to 9 × 9 in., 1 in. thick. They are laid over membrane waterproofing on flat roofs, with elastic-filled expansion joints around all parapets, penthouses, etc.

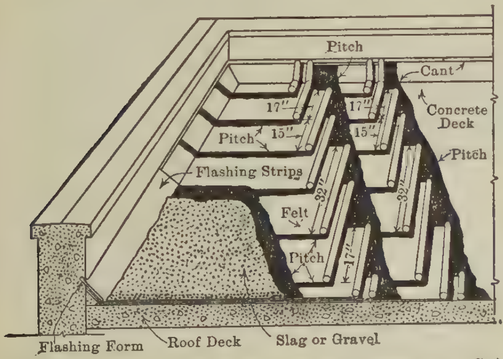

Fig. 23. Four-ply Membrane Roofing (*Barrett Mfg. Co.*)

**MEMBRANE ROOFING** in 3 to 5 layers, laid either with coal-tar pitch or asphalt, is standard roof waterproofing. Wearing surface on horizontal or slightly pitched roofs is slag or gravel; 200 lb. of pitch, 300 lb. of slag or 400 lb. of gravel are required per square.

**ASBESTOS SHINGLES,** made in a variety of sizes, colors and textures, are laid by two methods, hexagonal or French, and American. Hexagonal shingles usually are 12 or 16 in. square. The lower corner is cut off to give a honeycomb effect when laid. Average weight per square of $^{1}/_{8}$-in. thickness French laid is 275 lb.; average weight American laid is 565 lb. Asbestos corrugated roofing is used for pitched roofs of warehouses and industrial buildings.

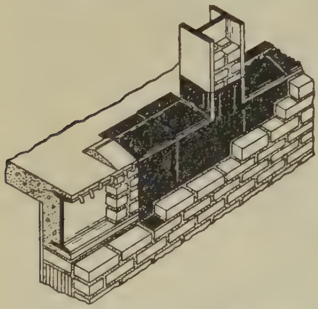

Fig. 24. Spandrel Beam Flashing (*Structural Waterproofing Co.*)

Three-ply roofing, guaranteed for 15 years, requires 175 lb. of pitch per square when laid on concrete. On wood roof decks, the first two plies are laid dry; a total of five plies then corresponds to and carries the same guarantee (20 yr.) as 4-ply work laid on concrete.

Roofs of industrial or commercial buildings used for recreation, use coal-tar pitch mixed at the factory with crushed limestone. It is laid cold, 1 $^{1}/_{2}$ in. thick, and later compacted to 1 in. by a 500-lb. roller.

**HEAVY FELTS,** impregnated with asphalt and surfaced with crushed minerals, are used as individual or strip shingles in a wide variety of colors and sizes. Standard sizes of individual shingles (American type) are 12 × 15 and 9 × 12 in., $^{3}/_{16}$ in. to $^{1}/_{4}$ in. thick. The 4-tab strips usually are 10 × 36 in.; when laid with a 2-in. head lap, weigh approximately 290 lb. per square.

**METAL ROOFING** for industrial buildings comprises corrugated iron sheets, tin and terne plate. See pp. 17–81 to 17–86.

**Copper, Lead** and **Zinc** sheets also are used on both flat and pitched roofs. Copper costs more than tin, but is more lasting. It is laid over a felt base with flat-locked seams on roofs of pitch less than 1 in 3, and with ribbed- or standing-seams on sloping roofs.

**Lead** is not used extensively, but lead-covered copper is occasionally used on monumental work. Zinc generally is cheaper than copper and has been used both as roofing and siding on industrial buildings. Corrugated sheets, 9 to 15 gage, weigh 79 and 187 lb., respectively, per square. No. 9 gage sheets with $^{7}/_{8}$-in. corrugations may be used with 30-in. purlin spacing; No. 15 gage, with a 78-in. purlin spacing.

**Aluminum** roofing in ordinary sheets, corrugated sheets and shingles, is laid by the same methods as other sheet metals. Thus, 24 × 96 in. No. 20 B. & S. gage sheets may be laid on wood battens 2 in. high.

All sheet metal roofs, particularly lead and zinc, must have provision for expansion. For additional information on weights of roofing materials, see p. 17–81.

**FLASHINGS** are required where roof surfaces intersect dormers, chimneys, vents, parapets, penthouses; beneath copings and sills; over lintels and cornices; and along valleys, ridges or built-in gutters; and in steel-frame buildings, over spandrel beams at each floor level.

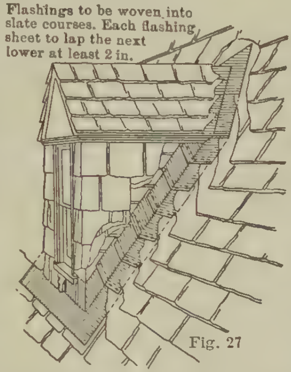
The Copper and Brass Research Assoc. recommends 16-oz. soft, roofing temper, copper sheet, laid on rosin-sized paper or asbestos felt, and cornice temper copper for cornice work only. Large loose-lock joints should be used at roof intersections. Finished dimensions of seams are: standing, 1 in.; flat-locked, $1/2$ in.; lapped, 1 in.; double or copper-locked, $1/2$ in. Joints should be tinned thoroughly with enough tin to cover the entire surface, using rosin as a flux, and plenty of best composition half-and-half solder. Seams should be thoroughly heated before soldering. Fastenings should be only cleats or strips fastened with copper nails. Bends should not exceed 90°.

Metal flashings for short open valleys should be 20 in. wide; for long valleys, 24 in. Roofing is lapped 6 in. over the copper, flashing being exposed for 8 in. along bottom of valley. To flash closed valleys insert under every course of slate or other roofing, a trapezoidal sheet of copper approximately 16 × 10 × 10 in.; exact size depends on length of slate and pitch of adjoining slopes. Each sheet should overlap below at least 3 in., and extend at least 2 in. above top of the slate or tile on which it rests. Hips and ridges may be protected by metal molds, or covered by additional courses of shingles or slate without flashing. Special shapes are made for ridges and hips of clay and cement tile.



Flashings to be woven into slate courses. Each flashing sheet to lap the next lower at least 2 in.

## 9. ROOF TRUSSES

**STRESSES IN ROOF TRUSSES** may be determined analytically or graphically. See p. 17–03.

**ALLOWABLE WORKING STRESSES,** when not controlled by a building code may be those in the Specifications for Structural Steel for Buildings. See p. 17–14.

**WOOD ROOF TRUSSES.**—The wood bow-string truss is economical for 25 to 100 ft. spans. Trusses usually are spaced 16 to 20 ft. centers. The required rise is about $1/8$ span. For a slow-burning classification, the size of web members is increased. If these trusses have sufficient fire-resistance, they usually are more economical than steel.

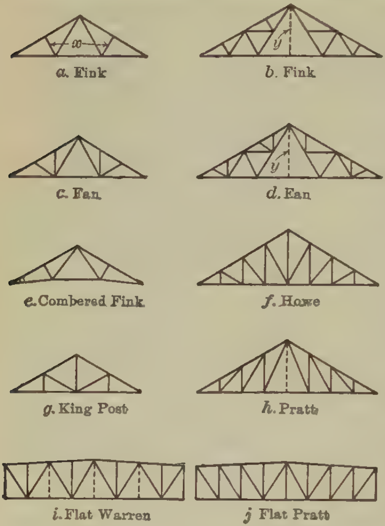
Many types of wood trusses are available for architectural designs. The best known are the hammer beam, scissors trusses and the crescent type; the Howe truss may be designed in wood with either a straight or curved lower chord.

**THE LAMELLA TRUSS** is a well-known patented design, built either of wood or steel. The sections of steel trusses are either pressed metal or standard structural shapes. For fireproofing, 2 in. of Gunite or precast gypsum tile can be used.

In wood designs, timber members range from 2 × 8 to 6 × 24 in., depending on span and load. They are assembled with standard bolts and washers. Four basically different structural types are: Segmental arch, tie rods taking thrust; segmental arch, heavy side walls or buttresses taking thrust; parabolic arch, buttresses taking thrust; gothic arch, thrust transmitted directly to foundations, which are supplemented by buttresses.

An advantage of the Lamella system is that the units are short and light weight. When of wood, they usually cost more than a steel truss. Lamella designs in steel cost approximately the same as steel trusses.

**STEEL ROOF TRUSSES.**—The **Fink Truss** and the **Fan Truss** are used for moderate spans. To lay out the Fink truss, Fig. 31*a*, draw a perpendicular *x* from center of top chord to lower chord; draw the other web members as indicated. In diagrams *b* and *d*, the lines *y* indicate sag rods, added for stiffness; theoretically they carry no stress. Panels in a half-truss may be increased to 4 by subdividing each panel, and to 8 by repeating the process. Fig. 31*c*, *d* shows construction of a fan truss.



*a.* Fink *b.* Fink *c.* Fan *d.* Fan *e.* Combered Fink *f.* Howe *g.* King Post *h.* Pratt *i.* Flat Warren *j* Flat Pratt

FIG. 31. Types of Roof Trusses

Fig. 31 shows other types of roof trusses. If trusses support purlins at panel points only, a good length for top-chord panels is 8 ft., corresponding to a maximum span of about 30 ft. for truss *a*, 40 ft. for *c*, 55 ft. for *b*, and 75 ft. for *d*. Warren and Pratt trusses may be used for long spans; the limit is the capacity of piers to carry end reactions.

Spacing of roof trusses depends on many factors. Arbitrary figures cannot be given. Bays of equal length are desirable in any one section of a building so that as many trusses as possible may be identical. For spans up to 60 ft., 15 to 18 ft. spacing usually is most economical for average loads; this spacing may be controlled by location of windows, piers, or architectural design. For spans over 80 ft., economical spacing may be 20 to 40 ft. To determine most economical spacing for the roof deck used, several designs should be made, including trusses, purlins and wind bracing.

**ARCH ROOF CONSTRUCTION,** usually of steel, is appropriate for spans of 100 ft. or more. The arches may be designed as hingeless, one-, two- or three-hinged arches; the two-hinged type predominates. Standard structural shapes and sizes are employed in a patented design with special connections. Spans from 100 to 200 ft. are the most common, but spans up to 400 ft. or more may be constructed with short lengths of the usual structural materials. The roof may be fireproof, fire-retardant or non-fireproof. Such designs are used for roofs of garages, exhibition halls, gymnasiums, armories and airplane hangars. Foregoing data were supplied by Arch Roof Construction Co.

**CONCRETE SHELL ROOF CONSTRUCTION,** identified as the Zeiss-Dywidag system, may be of the dome or barrel type, and can be applied to roofs of circular, rectangular or polygonal plan. Shell structures are essentially arched plates composed of reinforced concrete, and supported by the stiffening of their rims. They can be adapted with great economy to a variety of buildings where a large, unobstructed floor space is essential, such as planetariums, airplane hangars, market halls, train sheds, etc. By means of this system, shell domes spanning 500 ft., and shell vaults covering vast areas, without interior supporting columns, can be designed in reinforced concrete, which would otherwise be impossible, because of the dead load of the construction. Shell domes, approximately 250 ft. diameter, have been built with a shell thickness of only 3 $^{9}/_{16}$ in., and a barrel-shell concrete roof only 2 $^{3}/_{16}$ in. in thickness has been used on a span of 164 ft.

**GUASTAVINO TIMBREL ARCH CONSTRUCTION,** applicable to both domes and arches, comprises a shell composed of three or more layers of terra cotta tile, 1 in. thick, 6 in. wide, and 12 in. or 24 in. long. These are laid flat in cement mortar and bonded together to form a solid, homogeneous mass, which is reinforced with small steel rods where required. For ordinary 3-course work, the crown of the arch is about 4 in. thick. Domes may be constructed economically up to a span of 130 ft. or more. Hollow tile often are introduced within the thickness of the shell for insulation, and acoustical tile, for sound absorption, on the soffit of the arch or dome.

## 10. WATERPROOFING

**INTEGRAL WATERPROOFING** compounds are mixed with the concrete as liquids, pastes or powders. To some extent they lubricate the aggregate, producing a more workable mixture, reduce the capillarity of the hardened concrete and, in some cases more thoroughly hydrate the cement. Accredited compounds are of distinct value in producing watertight concrete and, if used according to the makers' directions, do not decrease strength. The first requisite is well-graded aggregate. Continuity at construction joints and avoidance of stone pockets or layers of laitance is necessary. Integral waterproofing will not cure poor materials, improperly graded aggregate or careless workmanship. Keys should be made at all construction joints; surfaces already cast should be roughened and slushed with rich mortar to insure a bond. A plastic mixture should be used, which can be thoroughly compacted, and sufficiently dry to avoid laitance forming on newly deposited surfaces.

**SURFACE COAT WATERPROOFING** may be classified as: 1. Plaster coat of cement mortar with or without waterproofing compounds; 2. Penetration surface treatments with inert liquids or liquids reacting chemically with the surface treated; 3. Plastic or liquid bituminous coatings; 4. Non-bituminous coatings forming a protective film on the surface. Classes 2 to 4 are used only for dampproofing. Class 1 consists in applying several coats of cement mortar (1 part cement, 2 parts well-graded sand with the addition of waterproofing compound). The base coat must be bonded to the concrete.

The process is: 1. Thoroughly roughen and wet the surface. 2. Work in a coat of neat cement with a brush or wooden float. 3. Before this grout is dry, apply a $3/8$- to $1/2$-in. coat of waterproof mortar, thoroughly trowelled and lightly scratch-brushed. 4. As soon as first coat is dry, apply a second coat, making a total thickness of $3/4$ in.; trowel to a smooth, hard finish with a steel trowel. For floors, total thickness of both coats is about 1 in. It is more practicable to carry waterproofing up the faces of the columns and partitions than under them. Recesses should be left at construction joints or other places susceptible to leakage, to be filled later with cement plaster reinforced with wire fabric to form a seal. The surface coat is low in cost, and has been applied to the inside surfaces of foundation walls of many large buildings.

**BITUMINOUS OR NON-BITUMINOUS SURFACE WASHES** are applied by a brush or mop. Two or three coats generally are used: a priming coat sufficiently liquid to penetrate the surface; the other coats are somewhat viscous. Such methods are successful for the exterior of basements where subdrainage precludes development of any hydrostatic head. They are not to be recommended where high water pressure is present.

**THE MASTIC METHOD** consists of applying either a sheet of mastic or a layer of brick laid in bituminous material. The brick are laid in two or more courses, one being completely surrounded by mastic. The outside courses often have a protective covering of concrete. This system is not widely used on building construction.

**THE MEMBRANOUS METHOD** uses a tar pitch or asphalt binder between layers of impregnated felt, jute, cotton drill or burlap. It is satisfactory, but often costly, as conditions usually make it impracticable on exteriors; if used on interiors, a concrete seal must hold the membrane in place. Membranes and sheet metals have the sole function of furnishing a more or less elastic waterproof filament and may be used where vibration precludes other methods. Before placing waterproof membrane, concrete surfaces should be pointed, fins removed, and subdrainage provided to insure dry surfaces for treatment. If dry surfaces cannot be obtained, waterproofing may be built over a layer of felt against the wall, although actual bond with the concrete is preferable.

Methods of laying membranes and the number of plies vary with conditions. Asphalt or pitch are satisfactory as binders; treated felt is cheapest, if elasticity is not required. For important work, particularly if elasticity is required, an open-mesh jute or cotton drill, $4\,1/2$ oz. per sq. yd., saturated in a bituminous mixture, is preferable. It should be used with an elastic binder, laid in 3-ft. squares, lapped a minimum of 2 in. on each edge. From 4 to 6 plies are used. Each layer of membrane should be carefully pressed into the binder and complete continuity obtained. Pipes passing through the membrane are fitted with copper or lead flanges extending into the waterproofing at least 1 ft. on all sides; for steam pipes a special detail is necessary to avoid melting the binder.

Two general schemes are used for membrane waterproofing: 1. Membrane is laid as a continuous mat over sub-floor, beneath columns, and carried up outside basement wall, where it is protected by a masonry seal. Below columns, or other members transmitting load, 20-oz. soft-rolled copper sheets extend 1 ft. on all sides into the membrane. 2. Membrane is not laid until columns and exterior walls are built. It is placed on the sub-floor and carried up column sides and exterior walls above the hydrostatic head, and protected with a masonry seal.

It is necessary in either case to build a seal over the basement floor strong enough to resist the pressure. For low heads a gravity seal may be used, but usually the floor is built as a horizontal slab, reinforced against uniform upward pressure and held in place by the columns and wall loads.

## 11. ESTIMATING

Accurate estimates of building costs should be made only from actual cost records on similar work. Quantities of materials for various types of construction can be obtained from handbooks, and material prices from local dealers. Labor costs, given in even the best handbooks, are practically of no value. The efficiency of all labor varies widely in different parts of the country, and standardization of man-hours for even the simplest operations is impossible.

**QUANTITIES.**—Accurate estimates must be based on a carefully made quantity survey. A clear idea of the job as a whole is obtained by visiting the site, reading specifications and studying drawings. Inconsistencies between drawings and specifications should be reconciled, and a definite plan of operation formulated for construction. Quantities are obtained by scaling drawings, in connection with specifications. All quantities are expressed in estimate units, as cu. yd. of excavation, cu. ft. of masonry, thousands of brick and sq. ft, of flooring.

Horizontal areas for excavation, floor construction, etc., and vertical areas for walls and partitions are determined from drawings and recorded. Columns are recorded in linear feet and their type and section noted. Inclined surfaces, as roofs, are computed on the superficial area; stairs and steps by number of treads and risers. The thickness of each element is obtained from drawings, and volumes computed where necessary. Window and door openings, stair and elevator wells, are deducted from gross wall and floor areas. These data are used later to schedule doors, windows or other frame-surrounded openings.

For example, consider concrete partitions. The lengths of all partitions, scaled from plans without deductions for small openings, and multiplied by heights read from the sections, give 1/2 the contact area of forms. Deducting from this quantity area of openings, and multiplying the difference by partition thickness, in decimals of a foot, gives the concrete volume. This same area multiplied by weight of reinforcement per square foot of partitions, is weight of steel in pounds. This area doubled, is the area in square feet for plastering or painting. Information already taken off gives number and size of doors and windows, which are subdivided by types. This last schedule gives linear feet of door frames and sills; from the list of doors and windows, hardware may be noted.

No great degree of accuracy is necessary in scaling quantities, but cumulative errors due to approximating quantities for units which repeat many times, should be avoided. Quantities should be tabulated on a quantity sheet under appropriate captions; these are the major divisions of work arranged in chronological sequence, as excavation, foundations, structural steel, floor arches, stone veneer, common brick, etc. After determining quantities and preparing a tentative plan of construction plant, a speed schedule is made.

**UNIT PRICES.**—Material prices should be carefully figured from quotations, to avoid error in this portion of the estimate. Labor prices must be obtained from previous experience on similar work. Material prices and probable cost of labor items, are multiplied by the quantities to obtain the cost of each item of the work.

**FINAL ESTIMATE** sheets should have separate columns for labor and material costs. Items of job overhead, as liability insurance, superintendent's salary, and plant rental charges are based either on time or percentages of direct labor and material costs. Subcontracts, which normally include heating and ventilating, plumbing, elevator installation, electrical work and sprinklers, may represent from 25% to 75% of total cost. Such items are recorded on the final estimate sheet following the tabulation of work performed by the builder's organization, with its accompanying overhead. The last item, profit or commission, usually a percentage of preceding items, completes the final estimate.

**ESTIMATING COST BY CUBICAL CONTENT.**—For approximate estimates, it may be useful to price a building on a cubic foot basis. The following procedure is based on recommendations of the Am. Inst. of Architects.

The cubic content (cube or cubage) of a building is actual space enclosed between outer surfaces of outside walls and outer surfaces of roof and 6 in. below finished surfaces of lowest floors. This definition includes cube of dormers, pent houses, vaults, pits, enclosed porches and other enclosed appendages as a part of cube of the building. It does not include cube of courts or light shafts, open at the top, or cube of outside steps, cornices, parapets, or open porches or loggias.

Items listed separately are: *a.* Cube of enclosed courts or light shafts open at the top, measured from outside face of enclosing walls, and from 6 in. below finished floor or paving to top of enclosing walls. *b.* Cube of open porches measured from outside face of wall, outside face of columns, finished floor and finished roof. *c.* Square foot area of all stoops, balconies and terraces. *d.* Memoranda, or brief description, of caissons, piling, special foundations, or features, if any.

As a guide, the following cubic prices represent total construction costs, exclusive of engineering or architectural services. These figures are of value *only for the purpose of making crude approximations.*

**Multi-story Industrial Buildings,** reinforced concrete, 20 to 25 cts. per cu. ft.

**Office Buildings, Fire-resistant Construction,** cheaply finished, 50 to 60 cts. per cu. ft. Office buildings, fire-resistant construction, expensively finished, 60 to 90 cts. per cu. ft.

**Public School Buildings,** 25 to 40 cts. per cu. ft.

**Frame Residences,** 25 to 35 cts. per cu. ft.

**Non-fireproof Masonry Residences,** 35 to 50 cts. per cu. ft.

**Fire-resistant, Elaborate Residences,** 50 to 90 cts. per cu. ft.

# PROPERTIES OF STRUCTURAL MATERIALS *

## ROLLED STRUCTURAL STEEL

The tables on pages 17–50 to 17–72 give the dimensions, properties, safe loads, etc., of the more commonly used forms of structural steel. These tables are considerably condensed from those issued by the manufacturers, but present a sufficient range of sizes and weights to permit the engineer to make, at least, preliminary designs. For more detailed information, consult the handbooks issued by the Bethlehem Steel Company, Carnegie-Illinois Steel Corp., and other manufacturers. For a more comprehensive treatment of the theory of beams and columns, see pages 7–17 to 7–34.

## 1. BEAMS AND CHANNELS

**TABLES OF SAFE LOADS.**—The tables of safe loads on the various shapes of structural sections are based on a fiber stress $f$ of 18,000 lb. per sq. in., when the section is used as a beam. Most building codes permit a value of $f = 18{,}000$ for quiescent loads; a few prescribe $f = 16{,}000$. For moving loads, $f = 12{,}000$. Where the beam is subject to impact the value of $f$ should be largely reduced, the formula being

$$f_i = f\{1 + \sqrt{(2H/y) + 1}\} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [1]$$

where $f_i$ = extreme fiber stress, lb. per sq. in., due to a falling load; $f$ = extreme fiber stress due to the same load at rest; $y$ = deflection, in., due to the same load at rest; $H$ = height of fall, in.

If the load is concentrated at the center of the span, the safe load is one-half the value given in the tables. If the load is not uniformly distributed nor concentrated at the center of the span, the maximum bending moment must be used. The maximum stress, lb. per sq. in., in a beam is the quotient of the maximum bending moment, in inch-lb., divided by the section modulus. This quotient must not exceed the allowable fiber stress for the particular condition involved as explained above. The weight of the beam must be deducted from the loads given in the tables to obtain the net applied load.

**SHEARING VALUE OF WEB.**—In very short spans or with concentrated loads, a beam or channel may fail by shearing or buckling of the web. Maximum shear values for each size of section are given in the tables, and are based on a unit shearing stress $f_s$ of 12,000 lb. per sq. in. The following methods may be used to determine maximum safe loads, from the standpoint of web shear, the value of $f_s$ being taken on the gross area of the web. Let $V$ = maximum allowable web shear, lb.; $A$ = gross area of web, sq. in.; $t$ = web thickness, in.; $h$ = clear distance between flanges, in.; $f_s$ = unit shearing stress, lb. per sq. in. Then for $h \overset{=}{<} 60\,t$, $f_s = 12{,}000$; for $h > 60\,t$, where the web is not stiffened,

$$f_s = V/A \overset{=}{<} 18{,}000/\{1 + (h^2/7200\,t^2)\} \quad . \quad . \quad . \quad . \quad . \quad . \quad [2]$$

Safe shearing stress usually is taken as 12,000 lb. per sq. in., although some building codes limit it to 10,000 lb. per sq. in. Where loads produce shear exceeding the safe web crippling resistance, web stiffeners should be placed at points of support of concentrated loads and at suitable intervals.

**BUCKLING.**—Beams may fail from end crippling or buckling at the point where the beam rests on bearings of ordinary length, or from the application of concentrated loads. Let $B_c$ = $^1/_2$ distance over which concentrated load is applied, in.; $B_r$ = distance over which end reaction is applied, in.; $D$ = depth of beam, in.; $f_b$ = safe resistance of web to buckling, lb. per sq. in.; maximum value of $f_b$ should not exceed 15,000; $R$ = safe end reaction, lb.; $t$ = thickness of web, in.; $W$ = concentrated load, lb.

$$\text{If both flanges are fixed, } f_b = 18{,}000/[1 + \{(1/6000) \times (D/t)^2\}] \quad . \quad . \quad [3]$$

$$\text{If one flange is fixed, } f_b = 18{,}000/[1 + \{(1/3000) \times (D/t)^2\}] \quad . \quad . \quad [4]$$

$$R = f_b\,t\{B_r + (D/4)\} \quad . \quad . \quad . \quad [5] \qquad W = 2f_b\,t\{B_c + (D/4)\} \quad . \quad . \quad . \quad . \quad . \quad [6]$$

Formula [5] applies to any condition of loading. Formula [6] applies primarily to a single concentrated load, but it will apply to a system of concentrated loads if the sum of the distance $B_c < B_r$. Minimum distance between end of beam and point of application of concentrated load is $(B_c + B_r + D/2)$.

---

* Staff contribution.

**DEFLECTION.**—The deflection of a beam uniformly loaded, supported at the ends, is based on the fundamental formula

$$y = (5/384) \times (Wl^3/EI) \quad [7]$$

where $y$ = deflection, in.; $W$ = total uniformly distributed load, lb.; $l$ = length of beam, in.; $E$ = modulus of elasticity = 29,000,000 for steel; $I$ = moment of inertia about neutral axis, in.$^4$ For a fiber stress of 18,000 lb. per sq. in., and a length $L$, ft. = 12 $l$, this formula becomes

$$y = 0.01862\, L^2/2n = C'/2n \quad [8]$$

where $n$ = distance of extreme fiber from neutral axis, and $C'$ = deflection coefficient whose values are given in Table 1. For floor beams carrying plastered ceilings

$$y < \text{span length}/360.$$

**Table 1.—Deflection Coefficients, $C'$, for Structural Beams**

The deflection due to impact of a moving load falling on a beam supported at the ends is

$$y_i = y(1 + \sqrt{(2H/y) + 1} \quad [9]$$

where $y_i$ = deflection, in. due to falling load; $y$ = deflection due to same load at rest; $H$ = height of fall, in. It should be noted that where the weight of the beam is a real factor, observed results do not agree with this formula, and practical tests give values much lower than the formulas.

**BEAMS LATERALLY UNSUPPORTED.**—The tables presuppose that beams are supported against side yielding of the compression flanges, by tie rods or other means at intervals of not more than 15 × flange width. If the distance between lateral supports exceeds this amount the tabular safe loads must be reduced in accordance with the values in Table 2. If $l$ = unsupported length of beam, and $b$ = width of flanges, both in inches, the maximum ratio of $l/b$ is 40. The A.I.S.C. formula for compressive stress in flexure is

$$s_c = 20{,}000/\{1 + l^2/(2000\, b^2)\} \quad [10]$$

with full stress limited to 18,000 lb. per sq. in. up to a ratio of $l/b$ = 15.

**Table 2.—Allowable Safe Loads on Unbraced Structural Sections Used as Beams**

Values are percentages of tabular safe loads (see pp. 17–55 to 17–57 and 17–60) for various ratios of length of span to width of beam, $l/b$.

(Am. Inst. of Steel Construction Code, 1931)

| $l/b$ | Percent | $l/b$ | Percent | $l/b$ | Percent | $l/b$ | Percent |

**BEAM CONNECTIONS.**—Figs. 1 and 2 and Table 7, p. 17–61, show standard forms of beam connections. Fig. 1 shows the construction for the usual run of work, providing shearing and bearing values are adequate. Fig. 2 shows the type of construction recommended where the web is thin, the span is short, or concentrated loads are applied. Under such conditions the riveting of the outstanding legs should be investigated and, if necessary, additional values should be provided by larger rivets in a single row or by double rows in the wider legs.

One-sided connections, that is connecting angle on one side of the beam only, never should be used if they possibly can be avoided. Such connections should be made with 6 × 6 × $^7/_{16}$-in. angles with a double row of rivets in each leg. Such connections should not be used on beams larger than 18 in.

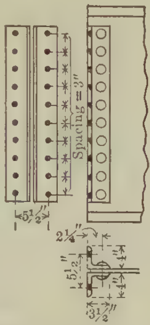

Fig. 1. Beam Connections, Usual Practice

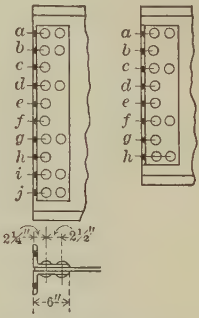

Fig. 2. Beam Connections for Short Span, Thin Web, or Concentrated Loads

**EXAMPLES IN BEAM DESIGN.**—The following examples show the use of the tables of properties and safe loads of standard rolled beams.

**1. Concentrated Loads.**—Required a beam, Fig. 3, of 20 ft. span to carry the following concentrated loads: $W_1$ = 6000 lb., 5 ft. from left support; $W_2$ = 8000 lb., 9 ft. from left support; $W_3$ = 4000 lb., 16 ft. from left support. Assume weight of beam at 50 lb. per ft. = $W_4$ = 50 × 20 = 1000 lb. The reactions are: $(R_1 \times 20) - (6000 \times 15) - (8000 \times 11) - (4000 \times 4) - (1000 \times 10) = 0$; whence $R_1$ = 10,200 lb.

$-(R_2 \times 20) + (6000 \times 5) + (8000 \times 9) + (4000 \times 16) + (1000 \times 10) = 0$; whence $R_2$ = 8800 lb.

Point of maximum bending moment or dangerous section is found as follows:

$(50 \times 5) + 6000 = 6250 < 10{,}200$; $(50 \times 9) + 6000 + 8000 = 14{,}450 > 10{,}200$; hence the dangerous section is at point of load $W_2$.

Maximum bending moment = $(10{,}200 \times 9) - (6000 \times 4) - (50 \times 9) \times 4.5 = 65{,}775$ ft.-lb.
or = $(8800 \times 11) - (4000 \times 7) - (50 \times 11) \times 5.5 = 65{,}775$ ft.-lb.

Based on a unit stress of 18,000 lb. per sq. in.,

Required section modulus = $(65{,}775 \times 12)/18{,}000 = 43.85$ in.$^3$

Referring to Table 5, the 12-in., 40.8-lb. beam has a section modulus of 44.8. It is satisfactory if the beam is braced against lateral deflection. If it is not feasible to brace laterally a heavier beam must be selected.

Three sections may be considered, viz., a 15 × 6-in., 60.8-lb. standard beam (Table 5), or a 12 × 8-in., 40-lb., or a 12 × 10-in., 53-lb. wide flange beam (Table 3).

Applying formula [10] to the 15 × 6 standard beam,

$$s_c = 20{,}000 / [1 + \{240^2/(2000 \times 6^2)\}] = 11{,}111 \text{ lb. per sq. in.}$$

Required section modulus $I/c$ = $(65{,}775 \times 12)/11{,}111 = 71.04$ (see p. 7–25.)

Similarly applying formula [10] to the other two beams:

For the 12 × 8-in. beam, $s_c$ = 13,793, and $I/c$ = 57.15; for the 12 × 10-in. beam, $s_c$ = 15,528 and $I/c$ = 50.48. The required section moduli are then compared with the actual section moduli as given in Tables 3 and 5, as follows:

| | 15 × 6-in. Beam | 12 × 8-in. Beam | 12 × 10-in. Beam |
|---|---|---|---|
| Required section modulus................ | 71.04 | 57.15 | 50.48 |
| Actual section modulus.................. | 81.2 | 51.9 | 70.7 |

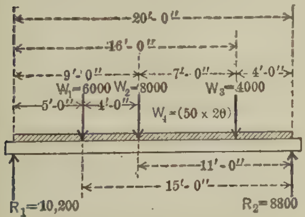

Fig. 3

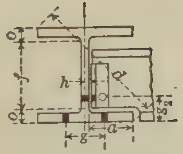
It is evident that the 12 × 8-in. beam is too light, but that either of the other two are satisfactory.

**2. Uniform Load.**—Select a beam to carry a uniform load of 30,000 lb. on a span of 16 ft., beam simply supported. Select a beam from Table 6. Opposite 16 ft. span, find the safe load of a 12 × 5 $^1/_4$-in., 40.8-lb. standard beam to be 33,600 lb. As this exceeds the specified load, it will be satisfactory.

The beam also may be selected by finding the maximum bending moment. For a uniform load, this is at the midpoint of the beam, and is (see Table 2, p. 7–22) $M = Wl/8 = (30{,}000 \times 16 \times 12)/8 = 720{,}000$ in.-lb.

Based on an allowable stress of 18,000 lb. per sq. in. $S$ = 720,000/18,000 = 40 in.$^3$. From Table 5 the section modulus of a 12-in. 40.8-lb. standard beam is 44.8 in., and the maximum safe load is $W = {}^2/_3(fS/L) = {}^2/_3\{(18{,}000 \times 44.8)/16\} = 33{,}600$ lb. Weight of the beam is 16 × 40.8 = 652.8 lb., which must be added to the load; 30,000 + 652.8 = 30,653 < 33,600 lb. Hence, the beam will be satisfactory. By the same form of calculation, a wide flange beam, 8 × 8 in., 48 lb., is found to be satisfactory.



## Table 3.—Properties of American Standard Wide Flange Beams

(Carnegie-Illinois Steel Corporation, Pittsburgh)

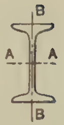
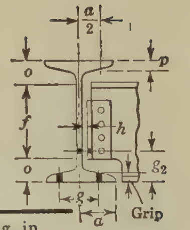
* Tabular values are for sections braced against lateral deflection. For unbraced sections, loads must be reduced. See p. 17–48.
Maximum bending stress, 18,000 lb. per sq. in.
Loads above upper horizontal lines will produce maximum allowable shear in webs.
Loads below lower horizontal lines will produce excessive deflections.
1 Kip = 1000 lb.



## Table 5.—Properties of American Standard Steel Beams

(Carnegie-Illinois Steel Corporation, Pittsburgh)



| Depth of Beam, in. | Weight per Foot, lb. | Area of Section, sq. in. | Flange | | Web Thickness, in. | Elements of Sections | | | | | | Dimensions for Detailing, in. | | | | | | | |

* Gages $g_2$ are based on 1 1/4 in. edge distance (7/8-in. maximum rivet.)

### Table 6.—Safe Uniform Loads on American Standard Beams

(Carnegie-Illinois Steel Corporation, Pittsburgh)

Applicable only when sections are braced against lateral deflection. For unbraced sections, see p. 17–48. Maximum and minimum weights only of each section are given. For intermediate weights, use the formulas on p. 7–22.

Loads above upper horizontal lines will produce maximum allowable shear in webs.

Loads below lower horizontal lines will produce excessive deflections.

* 1 Kip = 1000 lb.

## Table 9.—Safe Uniform Loads on American Standard Channels

(Carnegie-Illinois Steel Corp., Pittsburgh)

Applicable only when sections are braced against lateral deflection. Maximum bending stress, 18,000 lb. per sq. in. For safe loads for unbraced sections, see p. 17–48. Maximum and minimum weights of each section only are given. For safe loads of intermediate sections, apply the formulas on p. 7–22.

Loads above upper horizontal lines will produce maximum allowable shear in webs.

Loads below lower horizontal lines will produce excessive deflections.

---

* C60, 18 in. channel is a ship building channel, not American Standard.

† 1 kip = 1000 lb.

## 2. ANGLES, ZEES AND TEES

The properties of unequal and equal angles are given in Tables 12 and 13 respectively. Safe loads on angles used as beams are given in Tables 10 and 14.

**RADIUS OF GYRATION OF TWO ANGLES.**—The values of Table 16 for radii of gyration of two angles are employed for computing the safe resistance to compressive stress of

### Table 10.—Safe Uniform Load on Unequal Steel Angles Used as Beams.

Maximum, Intermediate and Minimum Weights
(Carnegie Illinois Steel Corporation, Pittsburgh)
Applicable only when sections are rigidly secured against lateral deflection
Maximum bending stress, 18,000 lb. per sq. in.

two angles placed back to back, used as a strut or the compression chord of a truss. The angles must be riveted or otherwise fastened together so that they act as a unit. The allowed stress per sq. in. corresponding to the ratio of $l/r$ of the section is obtained from the compression formula used, $r$ being taken from the table. The stress value so found is multiplied by the area of the two angles, the result being the allowable compressive stress.

Example.—Required the safe load in compression on a strut of two angles, 4 × 4 × 1/4 in., placed back to back; unsupported length, 9 ft. From Table 16, area of section = 3.88; least radius = 1.25; $l/r = 9 \times 12 \div 1.25 = 86.4$. Compression formula used,

$$f = 18{,}000 \div [1 + \{(l/r)^2 \div 18{,}000\}].$$

$$18{,}000 \div [1 + \{(86.4)^2 + 18{,}000\}] = 12{,}273 \text{ lb. per sq. in.}$$

Safe load = 3.88 × 12,273 = 49,365 lb.

**GAGES FOR ANGLES.**—Table 11 gives gages for punching or drilling angles for riveting, based on the standards of the American Bridge Co.

**Table 13.—Properties of Rolled Steel Equal Angles. Elements of Sections.**

## 4. COLUMNS

**SAFE LOADS.**—The tables of allowable loads on structural sections used as columns are based on the A.I.C.S. formula (revised 1928), which is

$$f = 18{,}000/[1 + \{(1/18{,}000) \times (l/r)^2\}] \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [11]$$

where $f$ = compressive unit stress, lb. per sq. in.; $l$ = unsupported length of column, in.; $r$ = least radius of gyration, in. The maximum unit stress at $l/r = 60$ is taken as 15,000 lb. per sq. in. The unsupported length of a column or main compression member should not exceed $120\,r$. Safe loads within this limit are between the heavy horizontal lines in the tables. Safe loads below the lower horizontal lines are for values of $l/r > 120$, and up to 200. They may be used for bracing and secondary members. The values given in the tables are for direct, central loads acting in the direction of the column axis.

**ECCENTRIC LOADING OF COLUMNS** produces bending stresses that must be taken into consideration. Columns must be so designed that the combined bending and compressive stresses do not exceed the values given by formulas [12] to [22].

Let $A$ = cross-sectional area of section, sq. in.; $d$ = distance of eccentric load from center of column, in.; $f_1$ = unit compressive stress for length $l$ of column, lb. per sq. in.; $f_2$ = unit compressive stress for length $l_2$ of column, lb. per sq. in.; $f_b$ = unit bending stress, lb. per sq. in.; $l$ = length of column, in. = $l_1 + l_2$; $l_1$ = distance, top of column to eccentric load, in.; $l_2$ = distance, bottom of column to eccentric load, in.; $M$ = maximum bending moment due to eccentric load, in.-lb.; $n$ = distance of extreme fiber from center of column, in.; $P_c$ = concentric load, lb.; $P_e$ = eccentric load, lb.; $r$ = radius of gyration of section in plane of bending, in. Then $P_c = Af_1$, and $P_e = Af_2$.

When eccentric load is applied above mid-point of column,

$$A = (P_c/f_1) + (P_e/f_2) + (P_e d\, l_2 n/l f_b r^2) \quad . \quad . \quad [12]; \qquad M = P_e d l_2/l \quad . \quad . \quad . \quad [13]$$

When eccentric load is applied at the mid-point of column,

$$A = (P_c/f_1) + (P_e/f_2) + (P_e dn/2 f_b r^2) \quad . \quad . \quad [14]; \qquad M = P_e d/2 \quad . \quad . \quad . \quad [15]$$

When eccentric load is applied below mid-point of column, the greater value of

$$A = (P_c/f_1) + (P_e d l_1 n/l f_b r^2) \ . \ [16], \text{ or } A = (P_c/f_1)+(P_e/f_2)+(P_e d l_2 n/l f_b r^2)[17]$$

$$M = P_e d l_1/l \quad . \quad . \quad . \quad [18]$$

When eccentric load is applied at top of column,

$$A = \{(P_c + P_e)/f_1\} + (P_e dn/f_b r^2) \quad . \quad . \quad . \quad . \quad [19]; \qquad M = P_e d \quad . \quad . \quad . \quad . \quad [20]$$

When eccentric load is applied at bottom of column,

$$A = (P_c/f_1) + (P_e dn/f_b r^2) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [21]; \qquad M = P_e d \quad . \quad . \quad . \quad . \quad [22]$$

**BENDING FACTORS.**—The bending factor offers a convenient means for converting bending moments produced by eccentric loads or other means, such as knee braces, into equivalent direct central loads. If the bending factor $k$ be multiplied by the bending moment, in.-lb., the product is an equivalent central load on the column, producing the same compressive stress as the bending moment. This equivalent load is added to the direct central load to give the total load that the column must carry. The proper size of columns then can be selected from the values of safe loads in the tables, opposite the proper figure for length of column. In formulas [12] to [22], $k$ can be substituted for the factor $(n/r^2)$.

**BASES.**—Steel slabs are preferable to iron or steel castings for column bases. Slabs should be designed to support a given section, when carrying a maximum load stressing the column up to 15,000 lb. per sq. in., with values of $l/r < 60$, with a maximum fiber stress in the slab of 18,000 lb. per sq. in. The commonly allowed intensities of pressure of the slab on good masonry are $w$ = 500, 625 and 750 lb. per sq. in. The size of the slab is computed as follows: $MN = P/w$; $t = p\sqrt{w/6000}$, where $M$ and $N$ = dimensions of slab, in., corresponding to width of flange $B$, and depth of section $D$, respectively; $P$ = total load on column, lb.; $w$ = unit pressure on slab support, lb. per sq. in.; $t$ = thickness of slab, in.; $p$ = projection, in., of slab beyond hypothetical column = $\frac{1}{2}(N - 0.95\,D)$, or $\frac{1}{2}(M - 0.80\,B)$, whichever is greater. Slabs thicker than 2 in. should be planed flat on their upper face to give a square bearing for the column, and on both faces if the slab is to rest on steel. If it is to rest on masonry or concrete, full bearing can be had by grouting with strong cement.

**EXAMPLE IN COLUMN DESIGN.**—The following are examples in the use of the tables for the selection of columns of rolled sections.

**1. Simple Concentric Load.**—Select a column 20 ft. long to carry a concentric load of 400,000 lb. *Solution.*—Refer to Table 21, opposite an effective length of 20 ft.; three columns are found to have

(*Continued on p.* 17–76)

## Table 21.—Allowable Concentric Loads on Wide-flange Sections Used as Columns

(Carnegie-Illinois Steel Corporation, Pittsburgh)

Maximum and minimum weights only of each section. Loads given in kips (1 kip = 1000 lb.). Unit stress based on formula of Am. Inst. of Steel Construction. See p. 17–73.

Safe loads above the upper zig-zag line are for ratios of $l/r$ not over 60; those between the zig-zag lines are for ratios of $l/r$ up to 120; those below the lower zig-zag line are for ratios of $l/r$ not over 200.

the requisite carrying capacity, *viz.*, CB 124, 12 × 12 in., 65-lb., 255,000 lb.; CB 143, 14 × 10 in., 74-lb., 258,000 lb.; CB 182, 18 × 8 3/4 in., 85-lb., 250,000 lb. Since CB 124 will carry the load at the least cost, it is selected.

**2. Concentric Load and Eccentric Load.**—Select a column 20 ft. long to carry a concentric load of 170,000 lb., together with an eccentric load of 27,500 lb. applied 4 ft. below the top of the column, and acting in the plane of greatest resistance, *i.e.* along axis AA, at a distance of 18 in. from the center of the column. *Solution.*—A preliminary selection is made of a 14 × 10-in., 74-lb. section, CB 143. From Table 3, the following data are derived: Area of section, $A = 21.76$ sq. in.; width of flange, $b = 10.072$ in.; radius of gyration $r$ about axis AA = 6.05; about axis BB = 2.48; distance to extreme fiber $n = 7.09$. From the conditions of the problem, $l = 20 \times 12$; $l_2 = 16 \times 12$; $d = 18$. (See notation for formulas [11] and [12]).

The unit compressive stresses are determined by formula [11] for both the concentric and eccentric loads.

$$f_1 = 18{,}000/[1 + \{(1/18{,}000) \times (20 \times 12/2.48)^2\}] = 11{,}842 \text{ lb. per sq. in.}$$

$$f_2 = 18{,}000/[1 + \{(1/18{,}000) \times (16 \times 12/2.48)^2\}] = 13{,}503 \text{ lb. per sq. in.}$$

Since the load is eccentric and applied above the mid-point of the column, formula [12] is used. Since the ratio $l/b = (20 \times 12)/10.125 = 23.70 > 15$, the unit fiber stress in bending, $f_b = 18{,}000$, must be reduced in accordance with the values of Table 2. Percentage of maximum unit stress corresponding to $l/b = 23.70$ is 86.78. Hence $f_b = 18{,}000 \times 0.8678 = 15{,}620$ lb. per sq. in.

Hence, applying formula [12],

$$A = \frac{170{,}000}{11{,}842} + \frac{27{,}500}{13{,}503} + \frac{27{,}500 \times 18 \times (16 \times 12) \times 7.09}{(20 \times 12) \times 15{,}620 \times (6.05)^2} = 21.32 \text{ sq. in.}$$

Since the area of the column selected is 21.76 sq. in., and an area of only 21.32 sq. in. is required, the selection is satisfactory.

**GRILLAGE.**—When grillage beams are used to support columns in order to distribute heavy loads properly upon soil bearing, the proper size of beams to be used in each tier is determined as follows: Maximum bending moment $M$, in ft.-lb., occurs at the center of the beam. $M = W(L - N)/8$, where $W$ = load supported by each beam in one tier, lb.; $L$ = length of beam, ft.; $N$ = length on which load is applied, ft. If $(L - N)$ be taken as the span, the size of, or safe load on, grillage beams may be obtained from the tables

(*Continued on page* 17–79)

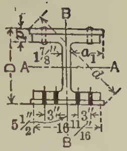
* Column core section.

Safe loads above upper zig-zag line are for ratios of $l/r$ not over 60; those between zig-zag lines are for ratios of $l/r$ up to 120; those below lower zig-zag line are for ratios of $l/r$ not over 200.



## Table 23.—Properties and Dimensions of Columns with Cover Plates

(Carnegie-Illinois Steel Corporation, Pittsburgh)

Column made up of wide-flange section CB 146–320 lb. with cover plates riveted to flanges. For allowable concentric loads, see Table 21

| Cover Plate | | Elements | | | | | | | | | | | Column Dimensions | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | | | Axis A–A | | | | Axis B–B | | | | | | | |

Safe loads above the upper zig-zag line are for ratios of $l/r$ not over 60; those between the zig-zag lines are for ratios of $l/r$ up to 120; those below the lower zig-zag line are for ratios of $l/r$ not over 200.

of safe loads on beams. If $(L - N)$ is less than spans given in tables, web shear or buckling governs, and the coefficient of strength or section modulus should be calculated.

$$C = W(L - N) \quad . \quad . \quad . \quad . \quad . \quad [23]; \quad S = 3W(L - N)/2f \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [24]$$

$$V_{\text{max.}} = W(L - N)/2L \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad [25]$$

where $C$ = coefficient of strength; $S$ = section modulus; $f$ = allowable unit stress in bending, lb. per sq. in.; $V_{\text{max.}}$ = maximum shear due to load $W$, lb. $V_{\text{max}}$ must not exceed allowable shear $V$. For computation of $V$, see formula [2]. The proper beam should satisfy formula [23] or [24], and formula [25].

## 5. RIVETING

Rivets usually are proportioned to transmit the entire stress, friction between the riveted members being disregarded. The number and size of rivets should be such as to give ample resistance to shear, and to give sufficient bearing area to avoid distortion of metal at the rivet holes. This latter condition sometimes requires increasing the thickness of webs of beams or girders. Table 25 gives shearing and bearing values of structural rivets. Machine-driven rivets may be calculated for higher unit stresses than hand-driven rivets, as shown in the tables.

### Table 25.—Shearing and Bearing Values of Rivets

| Rivet diam., in. | 1/2 | 5/8 | 3/4 | 7/8 | 1 | 1 1/8 | 1 1/4 | 1/2 | 5/8 | 3/4 | 7/8 | 1 | 1 1/8 | 1 1/4 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Rivet area, sq. in. | 0.1963 | .3068 | .4418 | .6013 | .7854 | .9940 | 1.2272 | .1963 | .3068 | .4418 | .6013 | .7854 | .9940 | 1.2272 |

**CONVENTIONAL SYMBOLS FOR RIVETING** are shown in Fig. 4, which represents American Bridge Co. standards. The diagonal cross represents a countersink, the blackened circle represents a field rivet, and the diagonal stroke a flattened head. The position of the cross, with respect to the circle (inside and outside or both sides), indicates

### Table 26.—Length of Rivet Required for Various Grips

(Am. Inst. of Steel Construction Standard)

## 6. ROOFING MATERIALS

**TERNE ROOF CONSTRUCTION.**—The following data were supplied by N. G. Taylor Co., Philadelphia: Roofs with less than $^1/_3$ pitch are made with flat seams, and preferably should be covered with 14 × 20-in. sheets, rather than with 20 × 28-in. sheets, as the larger number of seams tend to stiffen the surface and prevent buckles. For a flat seam roof the edges of the sheets are turned $^1/_2$ in., locked together and soldered. The sheets are fastened to the sheathing boards by cleats 8 in. apart and locked in the seams. Two 1-in. barbed and tinned nails are driven in each cleat. Steep tin roofs should be made with standing seams and from 28 × 20-in. sheets. The sheets are first single or double seamed and soldered together in a long strip reaching from eave to ridge. The sloping seams are composed of two "up stands" interlocked at the upper edge and held to the sheathing boards by cleats. No solder is used in standing seams as a rule. In soldering tin roofs, only a good rosin flux should be used. The use of acid must be carefully avoided.

**TIN PLATES** are made of soft sheet steel coated with tin, and are called in the trade "coke" or charcoal" plates according to the weight of coating. These terms have survived from the time when the highest quality of plate was made from charcoal-iron, while the lower grades were made from coke-iron. Plates to-day with the lighter coatings now are known as coke-plates, and are used for tin cans, etc. The various grades of charcoal-plates are designated by the letters A to AAAAA, the latter having the heaviest coating and the highest luster. One other brand, made with a heavier coating than 5A, is especially adapted for nickel-plating. The unit of value and measurement of tin plates is the "base-box," which is 112 sheets of 14 × 20 in. plate, or 31,360 sq. in. of any size. Plates lighter

| Terne plate, IX | 3/4 |
| Tiles (plain) 10 1/2 × 6 1/4 × 5/8 in.—5 1/4 in. to weather | 18 |
| Tiles (Spanish) 14 1/2 × 10 1/2 in.—7 1/4 in. to weather | 8 1/2 |
| White pine sheathing, 1 in. thick | 2 1/4 |
| Yellow pine sheathing, 1 in. thick | 3 1/2 |
| Zinc, No. 20 B. & S. Gage | 1 1/4 |

than 65 lb. per base-box (No. 36 gage) are known as taggers tin. No. 38 (55 lb. per base box) is the lightest plate regularly made.

**TERNE PLATES**, or Roofing Tin, are coated with an alloy of approximately 25% tin, 75% lead. The coating ranges from 40 lb. per box of 112 5A sheets to 20 lb. per box of 1A sheets and from 15 lb. to 8 lb. per box in other grades.

Terne plates are made in two thicknesses: IC, in which the iron body weighs about 50 lb. per 100 sq. ft., and IX, in which it weighs 62 1/2 lb. per 100 sq. ft. The IC grade is preferred for roofing, while the IX grade is used for spouts, valleys, gutters, and flashings. The standard weight of 14 × 20-in. IC plates is 107 lb. per base box, and of 14 × 20-in. IX plate 135 lb., with 8 lb. coating per double base box.

Long terne sheets are made in gages, Nos. 16 to 32, up to 48 in. wide and up to 144 in. long. They are made in three grades with coatings of "Regular," "Heavy," and 40-lb.

A box of 112 sheets 14 × 20 in. will cover approximately 180 sq. ft. of roof, flat seam, or 623 sheets 1000 sq. ft. For standing seam roofing a sheet 20 × 28 in. will cover 457 1/8 sq. in. or 316 sheets 1000 sq. ft. A box of 112 sheets 20 × 28 in. will cover approximately 356 sq. ft.

**TIN PLATE SPECIFICATIONS.**—(Condensed from U. S. Army Specification FXS No. 57—140A, December, 1929.) Applies to Grade A Light (Coke), Grade B Heavy (1A Charcoal) and Grade C Extra Heavy (2A Charcoal). Sheets to be of soft Bessemer or open hearth steel, or iron, free from laminations, blisters, slivers, open seams, scale pits, holes, and similar imperfections, and to be as uniform in thickness as practicable. Tin coating to be of commercially pure tin. Weights shall conform to Tin Plate Gage

(See Table 29) and the net weight of the finished product shall conform to the tolerances in Table 32.

**Coating.**—Grade A, no specific weight; Grade B, average of not less than 1.80 lb. per base box; Grade C, average of not less than 2.30 lb. per base box.

**Bending and Seaming.**—Sheets shall withstand bending cold through an angle of 180 deg., and flattening with a wooden mallet on a wooden block, without fracture on the outside of the bent portion; shall also stand double seaming without fracture across the direction of rolling.

**Squaring.**—Sheets shall not be out of square more than 1/8 in. per ft. Resquared sheets shall not be out of square more than 1/16 in., shall have no minus tolerance, and a plus tolerance of 1/16 in. in each dimension.

**LONG TERNE SHEET SPECIFICATIONS.**—(Condensed from U. S. Army Ordnance Department Specifications FXS No. 57—140B, November, 1929.) Base metal shall be either soft Bessemer or open hearth steel or iron, as ordered. Coated sheets of prime grade shall be free from laminations, blisters, slivers, open seams, mill scale, pit holes, and similar imperfections, and uncoated spots readily observable by the unaided eye. Seconds are sheets containing one or more of the above defects, and shall not exceed 20% of any one gage and size. A tolerance of 5% shall be allowed for sheets of one classification in a lot of another. All sheets shall be as nearly uniform in thickness as practicable; shall be commercially flat, and be as evenly coated on both sides as good mill practice will permit. Gage weights of coated sheets shall be those of the U. S. Standard Gage (see Table 12, p. 6–24).

**Tolerances in Dimensions.**—Sheets shall have no minus tolerance. Width of sheets shall not exceed that ordered by more than

1/4 in. for sheets ordered up to 36 in. wide and up to 120 in. long.
5/16 in. " " " " " 36 in. " " over 120 in. long.
3/8 in. " " " over 36 in. " " up to 120 in. long.
7/16 in. " " " " 36 in. " " over 120 in. long.

**Table 32.—Allowable Variation in Base Weight of Tin Plate**

| | Less than 272 lb. per Base Box * | 272 lb. to 544 lb. per Base Box † | Not Less than 544 lb. per Base Box † |
|---|---|---|---|
| All of one gage or base weight and size ‡ | ± 2.5% | ± 3.5% | ± 5.0% |
| If packed in single packages | ± 4.0% | ± 5.5% | ± 7.0% |
| Single sheets | ±10.0% | ±10.0% | ±10.0% |

* 20 oz. per sq. ft. † 40 oz. per sq. ft. ‡ Lots of not less than 6000 lb.

Length of sheets shall not vary more than 2% of the ordered length. Tolerances in weights of finished product will be as in Table 33.

**Table 33.—Allowable Variations in Base Weight of Terne Plate**

| Gage Range | | | | Permissible Variation in Weight of Sheets, Percentage of Theoretical Weight | | |
|---|---|---|---|---|---|---|
| Weight, oz. per sq. ft. | | Weight, lb. per sq. ft. | | | | |
| Less than | Not Less than | Less than | Not Less than | All of One Gage and Size in Shipment | Single Package | Single Sheet |
| .......... | 40 (No. 16) | ............ | 2.5 (No. 16) | ±5.0 | ±7.0 | ±10.0 |
| 40 (No. 16) | 20 (No. 22) | 2.5 (No. 16) | 1.25 (No. 22) | ±3.5 | ±5.5 | ±10.0 |
| 20 (No. 22) | .......... | 1.25 (No. 22) | ............ | ±2.5 | ±4.0 | ±10.0 |

**CORRUGATED SHEETS.**—Table 34 gives dimensions and weights of corrugated sheets, which are made in standard lengths of 5, 6, 7, 8, 9, and 10 ft.; maximum length, 12 ft. Covering widths of sheets, lapped one corrugation, are:

| | | | | | | |
|---|---|---|---|---|---|---|
| Covering Width, in.................... | 24 3/8 | 23 3/4 | 24 | 24 | 24 | 25 |
| Lap, in............................. | 5/8 | 1 1/4 | 2 | 2 1/2 | 3 | 5 |

Ordinary corrugated sheets should have a lap of 1 1/2 or 2 corrugations side lap and 6 in. end lap for roofing in order to make water-tight side seams; for siding, 1 corrugation side lap, and 4 in. end lap. Some manufacturers make a special high-edge corrugation on sides of sheets, and thereby are enabled to secure a waterproof side lap with one corrugation only, thus saving from 6% to 12% of material to cover a given area.

No. 28 gage corrugated iron is generally used for applying to wooden buildings; but for applying to iron framework No. 24 gage or heavier should be adopted.

Galvanized steel is about 2 1/2 oz. per square foot heavier than uncoated flat sheet steel of the same gage number.

**CORRUGATED ARCHES.**—For corrugated curved sheets for floor and ceiling construction in fireproof buildings, No. 16, 18 or 20 gage iron is commonly used, and sheets may be curved from 4 to 10 in. rise—the higher the rise the stronger the arch. By a series of tests it has been demonstrated that corrugated arches give the most satisfactory results with a base length not exceeding 6 ft., and 5 ft. or even less is preferable where great strength is required. These corrugated arches are made with 1 1/4 × 3/8, 2 1/2 × 1/2, 3 × 3/4, and 5 × 7/8 in. corrugations, and in the same width of sheet as above mentioned.

**SLATE.**—Slate in roofs is measured by the square, 1 square being equal to 100 superficial square feet. In measuring, the width of the eaves is allowed at the widest part.

* Siding. † Roofing.

Hips, valleys, and cuttings are measured lineally and 6 in. extra is allowed. The thickness of slate for roofing ranges usually from $^1/_8$ to $^3/_{16}$ in. The weight ranges, when lapped, from 4 $^1/_2$ to 6 $^3/_4$ lb. per sq. ft. The laps range from 2 to 4 in., 3 in. being the standard. As slate usually is laid, the number of square feet of roof covered by one slate is $w\ (l - 3) \div 288$, $w$ and $l$ being the width and length respectively of the slate in inches.

**Table 35.—Number and Superficial Area of Slate for One Square of Roof**

| Size, in. | No. per Square | Area, sq. ft. | Size, in. | No. per Square | Area, sq. ft. | Size, in. | No. per Square | Area, sq. ft. | Size, in. | No. per Square | Area, sq. ft. |

**Table 36.—Weight of Slate, in Pounds, for One Square of Roof**

(1 cu. ft. slate = 175 lb.)

| Length of Slate, in. | Thickness of Slate, in. | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | $^1/_8$ | $^3/_{16}$ | $^1/_4$ | $^3/_8$ | $^1/_2$ | $^5/_8$ | $^3/_4$ | 1 |
| 12 | 483 | 724 | 967 | 1450 | 1936 | 2419 | 2902 | 3872 |
| 14 | 460 | 688 | 920 | 1379 | 1842 | 2301 | 2760 | 3683 |
| 16 | 445 | 667 | 890 | 1336 | 1784 | 2229 | 2670 | 3567 |
| 18 | 434 | 650 | 869 | 1303 | 1740 | 2174 | 2607 | 3480 |
| 20 | 425 | 637 | 851 | 1276 | 1704 | 2129 | 2553 | 3408 |
| 22 | 418 | 626 | 836 | 1254 | 1675 | 2093 | 2508 | 3350 |
| 24 | 412 | 617 | 825 | 1238 | 1653 | 2056 | 2478 | 3306 |
| 26 | 407 | 610 | 815 | 1222 | 1631 | 2039 | 2445 | 3263 |

**Terra Cotta.**—*Porous terra cotta* roofing 3 in. thick weighs 16 lb. per square foot and 2 in. thick, 12 lb. per square foot.

**Ceiling** made of the same material 2 in. thick, weighs 11 lb. per square foot.

**TILES.—Flat tiles** 6 $^1/_4$ × 10 $^1/_2$ × $^5/_8$ in. weigh from 1480 to 1850 lb. per square of roof (100 square feet), the lap being one-half the length of the tile.

**Tiles with Grooves and Fillets** weigh from 740 to 925 lb. per square of roof.

**Pan-tiles** 14 $^1/_2$ × 10 $^1/_2$ laid 10 in. to the weather weigh 850 lb. per square.

**SHINGLES.**—Pine shingles are 16 in. long, 2 $^1/_4$ to 14 in. wide, and $^5/_{16}$ in. thick at the butt by $^1/_{16}$ in. thick at the thin end. Cypress shingles are 16 in. long and $^2/_5$ in. thick at the butt. In laying, 4 in. of the shingle are exposed to the weather.

The figures below give the weight of pine shingles required to cover one square of a common gable roof. For hip roofs add 5%.

| | | | | | |
|---|---|---|---|---|---|
| Inches exposed to weather.................... | 4 | 4 $^1/_2$ | 5 | 5 $^1/_2$ | 6 |
| No. of shingles per square of roof.............. | 900 | 800 | 720 | 655 | 600 |
| Weight of shingles per square, lb.............. | 216 | 192 | 173 | 157 | 144 |

**Table 37.—Skylight Glass Required for One Square of Roof**

| | | | | |
|---|---|---|---|---|
| Dimensions, in...................... | 12 × 48 | 15 × 60 | 20 × 100 | 94 × 156 |
| Thickness, in......................... | $^3/_{16}$ | $^1/_4$ | $^3/_8$ | $^1/_2$ |
| Area, sq. ft.......................... | 3.997 | 6.246 | 13.880 | 101.768 |
| Weight per square, lb................. | 250 | 350 | 500 | 700 |

No allowance has been made in the above figures for lap. If ordinary window-glass is used, single thick glass (about $^1/_{16}$ in.) will weigh about 82 lb. per square, and double thick glass (about $^1/_8$ in.) will weigh about 164 lb. per square, *no allowance being made for lap.* A box of ordinary window-glass contains as nearly 50 square feet as the size of the panes will admit. Panes of any size are made to order by the manufacturers, but a great variety of sizes are usually kept in stock, ranging from 6 × 8 in. to 36 × 60 in.

ROOF PAINTS (American Sheet & Tin Plate Co., 1932).—All sheets should be clean, to give close contact of paint and metal. Uncoated sheets should be free from mill oxide and rust, and if necessary, wire brushed and wiped with turpentine or gasoline. Grease and oil may be washed off with naphtha or toluol. Terne coated (roofing tin) is best wiped with benzine, turpentine, or benzol to remove the oil film. Zinc coated (galvanized) is best prepared by simple exposure to the weather for a few months. New zinc coated sheets first should be brushed with a solution of 4 oz. copper sulphate, copper chloride, or copper acetate in 1 gal. water, and after drying brushed lightly. Better results may be obtained by cleaning with a solution of 200 parts water, 30 parts trisodium phosphate, and 4 parts sodium hydroxide, all by weight, at 140 to 180 deg. F., then washing with hot water, followed by etching at room temperature for about $^1/_2$ min., with a solution of 1000 parts water, 200 parts hydrochloric acid, and 20 parts ammonium nitrate, all by weight, and then washing and thoroughly drying.

The weather should be clear and dry and the paint preferably applied in the afternoon, as it is essential that the surface be moisture free. Coat the surfaces in laps with fairly thick priming paint as the sheets are placed in position. The priming coat should be thin enough to fill and wet all parts. The finish coat should be thicker. Not less than two coats should be applied, with time for drying between coats.

Paint applied to sheet metal should be rust inhibitive. The priming coat should have as a basic pigment, red lead, lead chromate, or zinc chromate. Zinc dust and zinc oxide, 3 or 4 to 1, make efficient paint both for priming and finishing, especially as primer for galvanized sheets. Iron oxide paint is used for priming, but much better protection is obtained if it contains 10% or more of basic or chromate pigment, as zinc oxide, red lead, or zinc chromate. The pigment for the finish may be any good moisture excluder of suitable color. Linseed oil, preferably boiled, is a good vehicle for pigment, and excessive dryer should not be used. Boiled linseed oil or durable mixing varnish as part of the last coat adds to gloss and water resistance. It is economy to use only the best grades of paint for metal work.

# INDUSTRIAL HEATING PROCESSES

## INDUSTRIAL FURNACES*

**By W. Trinks**

**References.**—Bullens, Steel and Its Treatment (John Wiley & Sons); Trinks, Industrial Furnaces (John Wiley & Sons), Vols. I and II; Mawhinney, Practical Industrial Furnace Design (John Wiley & Sons); monthly publication *Industrial Heating*, Pittsburgh, Pa.

Many shop processes require the application of heat to solid material without melting it. The process, known as industrial heating, is carried on in industrial furnaces. The charge or stock usually is metal, but occasionally is a ceramic material. For iron or steel, the temperature ranges given in Table 1 are used. For other metals, temperatures well below their melting points are used. For the latter values, see p. 1–05 or Fig. 1.

### 1. FURNACE CHARACTERISTICS

**CLASSIFICATION OF FURNACES.**—Furnaces are classified: 1. According to use, as heating furnaces, forge furnaces, annealing furnaces, bright-annealing furnaces, heat-treating furnaces, and normalizing furnaces.

2. According to material or shape which they heat, as: rivet furnaces, bolt heading furnaces, plate furnaces, and angle furnaces.

3. According to the method of movement of the charge in the furnace, as: batch-type, also called in-and-out type, continuous furnaces, automatic or continuous-conveyor furnaces, rocker-bar or intermittent-conveyor furnaces, rotating hearth, car-type, and revolving drum.

4. According to the fuel or other source of heat energy, as combustion type, gas-fired, oil-fired, coal-fired, electrical resistor type.

5. According to the method of fuel saving, as: regenerative, recuperative, preheating-chamber type.

In muffle furnaces, the charge is heated in a gas-tight enclosure, and is separated by it from the source of heat.

**ECONOMY OF HEATING** must be based on unit weight of perfect product. The latter term involves such features as freedom from internal cracks caused by too rapid heating, uniformly high quality of heat-treated products, uniform annealing, uniform enamel of first quality, proper distribution of hardness, freedom from scale and ashes, freedom from burning of high-carbon steels, etc. In certain operations, such as plate bending, railroad spike forming, bolt heading and tool hardening, uniformity of temperature throughout the heated stock is not necessary.

---

* Nomenclature used in this section is as of 1937. Two separate committees are at present engaged in standardizing nomenclature.

**Table 1.—Furnace Temperature Range for Industrial Processes on Iron or Steel**

| Process | Temperature Range, deg. F. | Process | Temperature Range, deg. F. |
|---|---|---|---|
| Hammer or press welding | 2350 to 2550 | Hardening carbon steel (quenching) | 1450 to 1550 |
| Hardening high-speed steel * | 2200 to 2400 | Annealing cold-rolled steel | 1250 to 1400 |
| Drop forging | 2250 to 2370 | Drawing | 1150 to 1200 |
| Rolling (low carbon steel) | 2150 to 2275 | Nitriding | 950 |
| Bending and rough forming | 1900 to 2100 | Tempering | 500 to 800 |
| Normalizing, also for carburizing | 1650 to 1750 | Bluing † | 500 to 650 |
| Rough annealing | 1500 to 1650 | | |

* Special steels require various temperatures for hardening, usually ranging from 2400° F. for greatest hardness to 1850° F. for greatest toughness (for tungsten steel).

† Still lower temperatures are used for drying and japanning.

True heating economy is inversely proportional to total cost per unit of product. It can be expressed by

$$E = W \div (I + M + L + F),$$

where $E$ = true heating economy; $I$ = interest on investment; $M$ = cost of maintenance; $L$ = cost of labor, including overhead; $F$ = cost of fuel; $W$ = unit weight of perfect product.

The amount of capital which profitably can be invested in a furnace installation depends upon regularity and quantity of output of heated material. Cost of maintenance, $M$, depends on furnace temperature, furnace design, selection of refractories, care used in operation, and on cost per unit of labor and materials used in repairs. Cost of operating labor, $L$, depends on regularity of production with regard to continuous output, size and shape of stock, and on the provision of labor-saving equipment conjointly with unit cost of labor per hour. Cost of fuel or energy, $F$, depends on heating temperature, heating process, unit cost of fuel or energy, furnace design, and care used in operation. Frequently the importance of fuel cost is overemphasized at the expense of the other items (including quality of finished product), because it is more readily amenable to calculation.

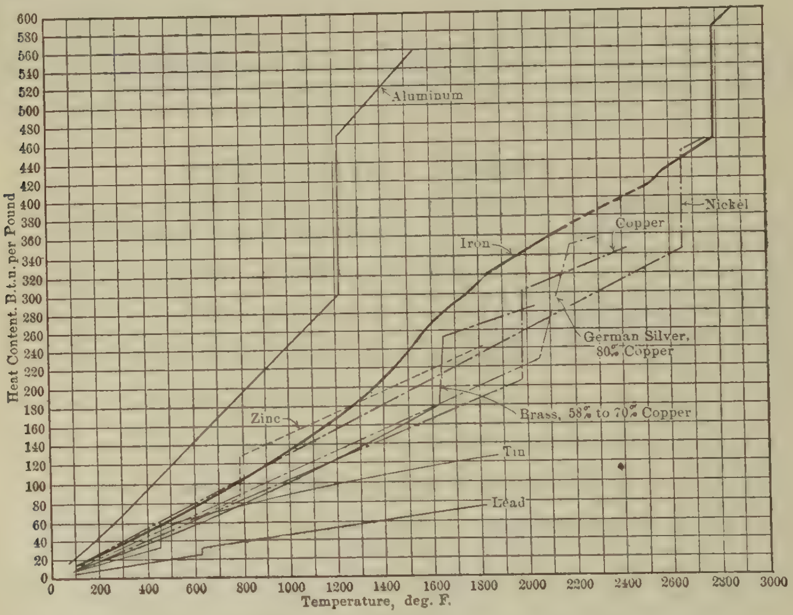

Fig. 1. Heat Content of Metals at Various Temperatures

**DISTRIBUTION OF HEAT.**—The potential heat energy of the fuel (or other source of heat) is distributed as follows: 1. Useful heat in charge. 2. Heat unavailably stored in the furnace walls. 3. Heat losses through solid walls. 4. Heat radiated through openings. 5. Heat to cooling water. 6. Unconsumed combustible in refuse. 7. Sensible heat in stack gases. 8. Combustible matter in spent gases. 9. Heat conducted through resistor terminals in electric furnaces.

Heating requirements and heating processes are so different that all of these items vary within wide limits. In electrically-heated furnaces, items 6, 7, and 8 are absent. The fuel consumption per unit weight of heated material can be computed by detail calculation of each of the eight items. While this method is followed for large furnaces, it seldom is used for the average type and size of industrial furnaces. Frequently, fuel consumption is divided into *holding consumption* and *useful consumption.* The former, also called *furnace constant*, is the rate at which fuel or energy must be supplied to keep the empty furnace hot.

The human element and variations in use of furnace cause excessive variations of fuel or energy consumption per unit of heated material. For that reason, the data contained in Table 2 are rough averages only. The unit fuel consumption may be as low as 60% of the values in the table, or may exceed them by 100%.

In furnaces which operate only during the day and are allowed to cool down over night, much heat is lost by storage in, and later dissipation from, the firebrick walls. In such cases, insulating refractories should be used. These weigh about one-third as much and have only one-third of the thermal conductivity of firebrick. When firebrick is replaced by the insulating refractories, the time required for heating up the furnace before starting work in the morning usually is reduced between one-third and one-fourth of the time required with firebrick walls. The fuel consumption for heating up is reduced in about the same proportion. In furnaces which are shut down at night the wall losses usually are about $1\,^1/_2$ times the heat imparted to the charge, depending, however, on the rate of heating in pounds of metal per square foot of hearth area per hour. The use of insulating refractories thus effects a saving of about 40% in the daily fuel consumption.

**CAPACITY OF FURNACES.**—The number of furnaces, and the size of each furnace, which are required to heat a given weight of metal to a given temperature in a given time, depend on several variables, as: 1. Thermal conductivity and specific heat of metal. 2. Requirements for uniformity of temperature in charge. 3. Rate at which heat may be applied without injury to stock. 4. Ratio of surface of charge to mass. 5. Ratio of brick surface to exposed surface of charge. 6. State of subdivision of charge. 7. Circulation of furnace gases. 8. Method of heat liberation, and size of heat liberating devices. 9. Cycle of operation of heating process. 10. Arrangement of charge in furnace. In determining number and size of furnaces, total hearth area required is determined from the following rules, and then is subdivided into standard size units to suit plant conditions.

In view of the great number of variables, the following practical rules for furnace capacity must be used with great care:

1. In iron or steel, heat penetrates at the rate of $^1/_8$ in. in five minutes. A plate $^1/_4$ in. thick, suspended in a furnace, practically assumes furnace temperature in the center of the plate after five minutes. This rule was derived from forging practice, and is sufficiently accurate for practical purposes so long as the temperature is not much higher or lower than forging temperatures. In brass, temperatures are equalized twice as fast, in aluminum six times as fast, and in copper nine times as fast as in steel, but in spite of this fact, the rate at which these metals can be heated, per square foot of furnace hearth area per hour, usually is less than for steel. This is because the absorption of radiant heat is reduced by the smooth surfaces of these metals. Black copper surfaces, however, absorb heat almost as rapidly as oxidized steel surfaces.

2. Forging ingots are heated at the rate of 16 to 20 min. per inch of diameter if of soft steel, and at the rate of 30 to 40 min. per inch of diameter if of high-carbon or alloy steel. Certain steels are very sensitive to temperature changes at "blue brittleness" (around 500° to 800° F.). After they show color all through, they cannot be injured by rapid heating.

3. In ordinary furnaces, steel can be treated at the rate of 25 to 35 lb. per sq. ft. of hearth area per hour for heat treating; at the rate of 60 lb. for annealing; 80 lb. for uniform temperature forging and rolling; and 110 to 130 lb. for work in which 40° to 50° F. temperature difference per inch of thickness of stock is allowable.

4. Steel for drop forging can be heated at the rate of 5 to 10 min. per in. of diam.

**Table 2.—Average Fuel Consumption of Industrial Furnaces**
(Material heated is steel, excepted where otherwise noted)

| Type of Furnace and Operation | Highest Temperature to which Stock is Heated, deg. F. | B.t.u. in Fuel per Pound of Material Heated | Thermal Efficiency, percent |
|---|---|---|---|
| Drop forging or bolt heading furnace, oil fuel | 2300 | 3200 | 11 |
| Bolt heading furnace, coal fired | 2100 | 6000 | 6 |
| Ingot forging furnace, in-and-out type, oil fired | 2200 | 2500 | 14 |
| Ingot forging furnace, in-and-out type, regenerative, gas fired | 2200 | 1900 | 18 |
| Mill-type continuous furnace | 2200 | 1100 | 32 |
| Mill-type continuous furnace, recuperative | 2200 | 900 | 39 |
| Car type annealing furnace for castings | 1600 | 1200 | 21 |
| Annealing furnace for brass | 750 | 750 | 10 |
| Case-hardening (carburizing) furnace | 1700 | 2500 | 11 |
| Heat-treating (quenching) furnace | 1400 | 1150 | 19 |
| Heat-treating (tempering) furnace | 1150 | 800 | 20 |
| Enameling furnace (muffle) | .... | .... | 15 |
| Electric heat-treating furnace | 1500 | 2500 | 80*; 10† |

* Based on electrical energy. † Based on fuel.

5. The time in minutes required for heating high-speed steel tools for hardening to a depth of $d$ inches is $8.5\ (d)^{0.78}$, according to R. C. Deale. This does not include the preheating time, but only the time to heat from 1600° to 2375° F. If the tool is to be hardened throughout, $d = 1/2$ thickness.

Fig. 2 shows the relation between heating time, temperature of bar and furnace temperature. Fig. 3 shows the difference between surface temperature and temperature in the center of the bar per inch of diameter.

The preceding rules are based on furnaces in which enough heat can be liberated to maintain furnace temperature. The data below assist in checking heat liberating capacity.

**Heat Liberation.**—In electrically heated furnaces (resistor ribbon type), working with temperature of 1850° F., the input energy usually is limited to not over 3 kw. per sq. ft. of side wall plus roof, with nickel-chromium resistor material. Somewhat higher rates would be permissible since 1936, on account of better high temperature alloys, but these seldom are used in furnaces for this temperature range.

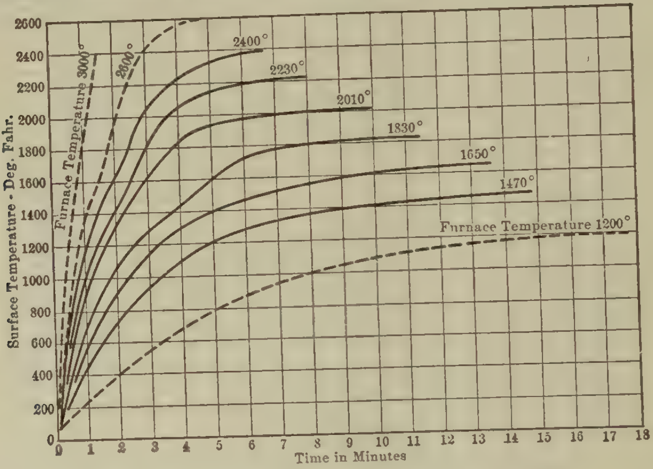

FIG. 2 Heating Time at Various Furnace Temperatures

In furnaces of the combustion type, from 1.5 to 33 B.t.u. can be liberated per cubic foot of combustion space per second. The low value applies to very poor mixing of fuel and air, very imperfect utilization of volume of combustion chamber by flame or gas jets, coarse fuel and cold air. The high value is attained by thorough mixing of fuel and air, perfect utilization of combustion space, very fine atomization or powdering of fuel, and air preheated to 1000° F.

**FLUES AND PORTS.**—If furnaces are properly proportioned, the following port sizes are approximately correct, based on steel as stock to be heated, and for 100 lb. per sq. ft. of hearth per hour. If a smaller quantity is to be heated, the outlet flues should be partly covered.

| | | | |
|---|---|---|---|
| Temperature of furnace, deg. F. | 1400 | 1800 | 2200 |
| Port area, square inches per foot of hearth | 2.0 | 3.5 | 7.3 |

These figures hold for "batch type" furnaces of medium size without recuperation or regeneration. For large and important furnaces, the ports and flues must be calculated on the basis of the flue gas quantity in unit time.

Ports should be located in or near the hearth, never in the roof. They should be so distributed as to cause flow of hot gases to all parts of the furnace. Some of the ports should be in the corners near the door or doors.

## 2. FUELS

**SELECTION OF FUEL OR ENERGY.**—The cost of fuel (or other sources of heat energy) is, in many instances, a very small fraction of the total cost of the manufactured product, and a minor fraction of the heating cost. In such cases, the effect of the form of heat energy on the finished product is most important, and the unit cost of energy is not a matter of consideration. In other cases, the fuel cost is a large item in the total cost, and cheapness of fuel is the deciding factor. The following tabulation, adapted from

Trinks, Industrial Furnaces, Vol. II, Chap. 6 (John Wiley & Sons), may be used in the selection.

The advantages and disadvantages of many of the fuels are denoted by numbers which have these meanings:

**Advantages.**—1. Heating value is high. 2. High flame temperature can be attained. 3. Pipe mains may be small because of 1. 4. Fuel can be burned efficiently. 5. Accurate temperature control is possible. 6. Accurate atmosphere control is possible. 7. Uniform quality of product is possible. 8. Damage to product is slight (few rejections of finished material). 9. Furnace installation is simple. 10. Cost of furnace installation is low. 11. Fuel cost based on heat units is low. 12. Fire risk is low. 13. Plant can be kept clean without difficulty. 14. Cost of upkeep of furnace may be kept low. 15. Labor cost is low (no handling of fuel and ashes). 16. Oxidation or scaling of heated material can be kept low. 17. Furnace is made ready for use by opening valve. 18. No fuel-preparation plant is needed.

**Disadvantages.**—19. Cost, based on heat units, is high. 20. Cost of installing gas-producing plant is high. 21. Installation is complicated. 22. Fuel supply is restricted. 23. Fuel requires handling. 24. Clinkers must be removed. 25. Ashes must be disposed of. 26. Cost of operating labor for gas making is high. 27. Heat value of fuel is low. 28. Large pipe mains are required because of 27.

**NATURAL GAS.**—Excellent fuel for all heating purposes. *Advantages:* 1 to 10 inclusive, and 12 to 18 inclusive. *Disadvantages:* Unreliability of supply, particularly in cold weather. Cost in most localities is rather high and the trend is upward.

**CITY GAS.**—Especially adapted to small-size and medium-size, high-grade, high-temperature work. *Advantages:* 1 to 10 inclusive, and 12 to 18 inclusive. *Disadvantages:* Fuel cost is very high. Gas is available only in cities with gas plants.

**WATER GAS.**—Valuable for high-grade, high-temperature work, in large-scale heating and welding operations, especially where high flame temperature must be produced without preheating the air. *Advantages:* 3 to 8 inclusive, 12, 16. Very high flame temperatures can be attained. Heat value is moderately high. Furnace room can be kept clean without difficulty. Items 5, 6, 7, 8, 16 depend on correct operation of the gas-making plant. *Disadvantages:* 19 (in small plants), 20, 21, 22 (coke or anthracite is required), 23, 24, 25, 26. Gas is odorless, but poisonous, and is a menace to life and health. Danger of backfiring, due to rapid flame propagation.

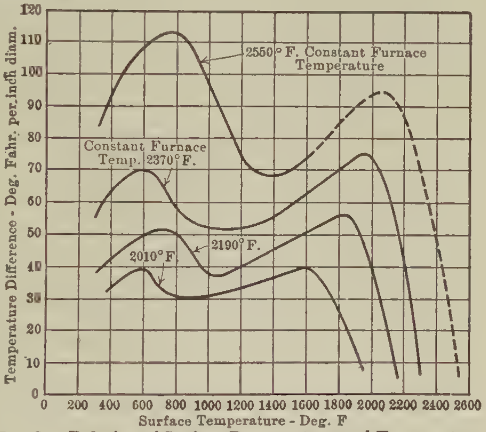

FIG. 3. Relation of Surface Temperature and Temperature at Center of Bar

**RAW PRODUCER GAS.**—The most commonly-used fuel for large furnaces in which close regulation of temperature and of furnace atmosphere is not required. *Advantages:* Cost on basis of heat units is low. Gas can be made wherever bituminous coal is available. Gas-making operation is comparatively simple. Gas burns with luminous flame. Installation cost is lowest of any gas-making equipment. *Disadvantages:* 22 (screened gas coal, for good results), 23, 24, 25, 27, 28 (brick-lined flues required). Furnace must be located close to producers, because not only do tarry vapors condense, but sensible heat of gas is lost in long pipe lines. Gas ducts become clogged with soot and tar, and must be burned out at regular intervals. Difficult to maintain constant quality and composition of gas. Difficult to keep intelligent workmen in dirty gas house. Steam plant required for furnishing steam to producers. Flow of gas can be measured only with difficulty, because of tar and soot deposits. Difficult manually, and practically impossible automatically, to control temperature and furnace atmosphere. Sulphur exists in the products of combustion.

**COLD CLEAN PRODUCER GAS.**—Efficient use of this gas is limited to about 2000° F., unless regenerative or recuperative furnaces are used. Useful for installations of large size only. *Advantages:* 4, 5, 6, 7, 8, 16. Temperature of combustion is low, which is desirable for furnaces with less than 1600° F. temperature. Long life of furnace, if properly designed and operated. Reliability of fuel supply. Stability of fuel cost. Gas burns without smoke, even if atmosphere is reducing. Fuel cost is comparatively low, in large installations. Gas can be distributed to many small furnaces. Advantages 5, 6, 7, 8, 16 depend on correct operation of the gas-making plant. *Disadvantages:* 20, 22 (screened gas coal) 23, 24, 25, 26, 27, 28. Installation is more complicated than with oil, city gas, or natural gas. Tar made in producers must be disposed of. Good furnace operation depends on zeal and skill on the part of the gas house operators.

**HEAVY FUEL OIL.**—Standard fuel for medium-size furnaces, except where convenient and cheap gaseous fuels are available. It is very viscous (7 to 12 Bé., 500 Saybolt viscosity at 100° F.) and usually contains sediment and dirt. *Advantages:* 1, 2, 10, 11. Convenience of handling and of storage. Simplicity of installation. Oil can be had anywhere. *Disadvantages:* Fluctuation of fuel cost. Furnace temperature and atmosphere difficult to control automatically. Possibility of damaging heated product, caused by temperature and atmosphere variations, or by impingement of flame. Fire hazards are high. Cost of labor is high because of constant attention required for burners and auxiliary equipment. Life of container boxes is likely to be short as compared with non-oxidizing gas fuel. Preheated air is required, if reducing atmosphere is to be obtained without excessive smoke. Recirculating system, heating and careful filtering of oil required. Life of furnace brickwork is shorter than for gaseous fuels.

**LIGHT FUEL OIL** usually is a distillate, and is quite fluid (24 to 40 Bé. gravity). It usually is free from sediment or dirt. *Advantages:* Same as for heavy fuel oil. Even more convenient to handle. Does not require heating, nor such great care in filtering. Installation is especially simple and inexpensive. Can be used in furnaces having many small burners; hence it is suitable for work requiring uniformity of product. Temperature can be controlled automatically. More suitable for fine work than heavy oil. *Disadvantages:* Fuel cost fluctuates, and usually is about 25% higher than for heavy oil, while the heat value per gallon is lower. Supply is limited. Atmosphere control is much more difficult than with gaseous fuels; hence there is greater danger of damage to product. Danger of burning product by impingement of flame (but less than with heavy oil). Fire hazard is high. Labor cost is higher than for gaseous fuels, because more attention is required for burners and auxiliary equipment. Life of container boxes and life of furnace brickwork is shorter than for gaseous fuels. Not so suitable as heavy fuel oil for furnaces requiring long, luminous flame, *e.g.*, open hearth.

Specifications for the six grades of fuel oil, standardized by the American Society for Testing Materials, are given in Table 3.

**COAL ON GRATES OR MECHANICAL STOKERS** can be used efficiently only for fairly continuous service and large furnaces. *Advantages:* Fuel cost is low. First cost of installation is low. Total operating cost is low if reliable heaters are employed, and suitable furnaces are used. Fuel supply is reliable. Fuel price is stable. *Disadvantages:* 23, 25. Firebox requires frequent repair. Floor space required is large. Competent firemen are needed, and difficult to keep. Scaling loss is high. Control of furnace temperature and atmosphere is difficult. A stack is required. Black smoke is produced if a reducing atmosphere is wanted. Sulphur exists in the products of combustion.

**COKE ON THE GRATE.**—Products of combustion are free from water vapor; hence they are very useful for heating drying-chambers. Gives high temperature and reducing atmosphere in open fire, without smoke; hence, is used for blacksmith forge fires. In all other respects, similar to coal on the grate.

**POWDERED COAL.**—At present (1937), useful in large furnaces only, because satisfactory small individual pulverizers have not yet been developed for powdering coal to sufficient fineness for combustion in industrial furnaces of average size.

*Advantages:* No labor is necessary to bring fuel to, or inject it into, the furnace. Control of temperature and control of furnace atmosphere are easy, as compared with coal on the grate. Fuel cost is low in large plants. *Disadvantages:* Flame temperature * is high. Combustion chamber difficult to maintain. Cost of pulverizing and coal equipment is high. Fine ash and slag must be disposed of. Recuperators or regenerators cannot be used. Explosion hazard in pulverizing plant. Ash deposits may spoil heated product, or floating in air of shop may damage machinery. Difficult to maintain an even temperature over a large hearth. Control of furnace atmosphere is difficult, as compared to gaseous fuels.

**ELECTRICAL ENERGY** is favored for many heating operations. *Advantages:* 5 to 9, 12 to 16, 18. Installation has great convenience and flexibility, including possibility of placing furnace anywhere. No products of combustion in furnace workroom. No piping or stacks required. Furnaces can be placed directly in the production line. Life of furnaces is long. Operation is simple. There is no auxiliary equipment of the kind that requires attention. Inconvenience to workmen in plant is a minimum. Furnace is made ready for use by closing a switch. Heat can be developed in the furnace hearth. *Disadvantages:* Cost, based on heat units, is very high. First cost of furnace and control is high. Furnace heats slowly from cold start. Cost of heat lost by storage in furnace walls is high in case of intermittent operation. Cost of repair is high. Delay results if resistors burn out. " Service " or " demand " charge of public utility is high in case of intermittent operation. Not suitable where high-temperature heating by convection is required.

---

* Whether high flame temperature is an advantage or disadvantage depends on the class of work. For low-temperature work, such as annealing, it is difficult with the rich fuels to keep the temperature low enough. For high-temperature work, such as welding, it is difficult to obtain sufficiently high temperature with lean fuels unless air and fuel are preheated.

**TAR AND COKE-OVEN GAS,** as a rule, are available only in steel plants. The former is similar to heavy oil, but more difficult to handle. Coke-oven gas is similar to city gas, but much cheaper.

**GASEOUS VS. LIQUID FUELS.**—Gaseous fuels are most convenient, particularly if drawn from large sources of supply (city gas, natural gas). They allow regulation within wide limits, easy control of air supply, scattered small burners for the sake of temperature control, and good control of furnace atmosphere. Regulation is more difficult if the furnace unit requires a large share of the capacity of the gas-generating plant.

Liquid fuels are not quite as convenient with regard to regulation as gaseous fuels, but they can be stored more conveniently. Gasoline and kerosene are used for very small heating operations only, while fuel oil is (in 1937) the standard fuel for medium-scale operations. For small-scale heating, heavy fuel oil is not suitable, because it must be

**Table 3.—Detailed Requirements for Fuel Oils**[a]

(A.S.T.M. Specifications)

Fuel oils are to be hydrocarbon oils free from acid, grit, fibrous or other foreign matter likely to clog or injure burner or valves.

| Grade | Flash Point, deg. F. | | Pour Point, deg. F. | Water and Sediment, per-cent | Carbon Residue, per-cent | Ash, per-cent | Distillation Temperatures, deg. F. | | | | | Viscosity, seconds | | | |

[a] For heat-treating and other special uses, sulphur may be specified:

| Grade of fuel oil........ | 1 | 2 | 3 | 4 | 5 | 6 |
|---|---|---|---|---|---|---|
| Sulphur, percent, max... | 0.5 | 0.5 | 0.75 | 1.25 | no limit | no limit |

[b] Lower or higher pour points may be specified, as required, but not below 0° F. under any conditions. [c] Lower or higher pour points may be specified, as required, but not lower than 15° F. under any conditions. [d] Shall be waived when carbon residue > 0.07% and < 0.15%. [e] Shall be waived when carbon residue > 1.0%. [f] A deduction in quantity shall be made for all water and sediment in excess of 1.0%. [g] Shall be waived when carbon residue is 4% or more.

heated and pumped, and because of the difficulty of maintaining uniformity of operation. With clean gas-oil, however, very uniform heating can be effected.

The relative cost of fuels is shown in Fig. 4. The broken line curve for city gas applies in cities having special rates for gas used for industrial purposes.

## 3. BURNERS

**OIL BURNERS.**—Oil burners atomize the oil, and should thoroughly mix it with air in definite proportions. They should maintain uniformly fine atomization with various rates of flow and varying viscosity of oil, and also should maintain the correct air-to-oil ratio under all conditions. These goals, practically, never are attained.

Mechanical atomizers which atomize by oil pressure only, as used for firing boilers, and rotary burners, as used in house-heating furnaces, seldom are applied to industrial furnaces, because they have insufficient turn-down range; also they give trouble from coke formation in the burner tip, when exposed to radiation from the hot furnace while the oil flow is shut off. The oil burners actually used for industrial furnaces, of which there are innumerable makes, fall into three general classes or types. The characteristics of these are discussed below.

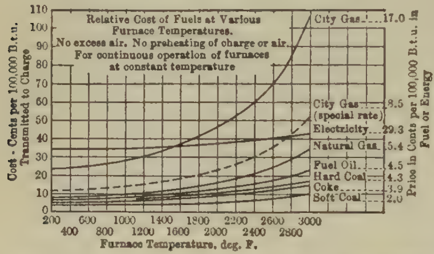

Fig. 4. Relative Cost of Fuels for Heating Furnaces

1. High-pressure burners, in which steam or compressed air at 30 to 150 lb. per sq. in. is used as the atomizing agent. An example is shown in Fig. 5.

2. Low-pressure burners, in which the atomization is effected by air supplied from a displacement- or turbo-blower at $^3/_4$ to 5 lb. per sq. in. Examples are shown in Fig. 6, *a* and *b*. In some burners of this kind, the oil pressure need be but slight, while in others, the pressure must be as high as in the following class of burners. The oil pressure helps atomization.

3. Fan-blast burners, in which atomization is effected chiefly by the pressure of the oil itself, from 30 to 150 lb. per sq. in. The energy of the air which is supplied by a fan at pressures of 4 oz. to 1 lb. per sq. in., is used merely for mixing the oil spray with the air, with some slight auxiliary effect in atomization. See Fig. 7.

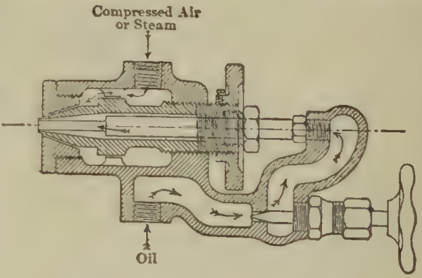

Fig. 5. High-pressure Oil Burner

Everything else being equal, higher air or steam pressures produce better atomization than low pressures, and require less of the atomizing agent under pressure. The heavier or more viscous the oil, the more difficult is atomization, and the higher is the pressure required. Light oil can be burned satisfactorily with fan-blast burners, but for the very heavy residues high-pressure burners are practically essential. Steam is preferable to compressed air for atomizing very heavy tar or oil, although it depresses the flame temperature slightly. The heavy oils must be heated to between 180° and 250° F. before atomization, and recirculated in order to maintain high temperature at the burner. If both oil and combustion air are sufficiently preheated, vaporization largely takes the place of atomization, and good, quick combustion can be obtained with low air pressure. However, cracking and coke deposition, or vaporization and sputtering

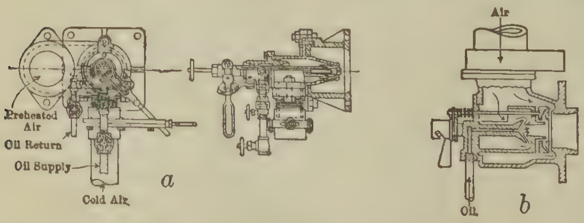

Fig. 6. Low-pressure Oil Burners

occur if the oil is heated too highly. High-pressure burners produce a long flame of comparatively small thickness; low-pressure burners produce a shorter, " bushy " flame. Flat instead of cone-shaped flames can be produced by suitable burners. Steam makes a longer flame than compressed air.

In fan-blast burners, atomization is effected by discharging high-pressure oil in a whirling spray through a small orifice. Fig. 8 shows an atomizing tip. In most of these burners, the range of turn-down is comparatively small, if satisfactory atomization is to be maintained, although in the best designs a turn-down of 5 to 1 is obtained. The very small openings required, except for very large units, clog easily unless gas oil is used, or efficient oil filters are provided in the case of heavy oil, and carbonization is entirely prevented.

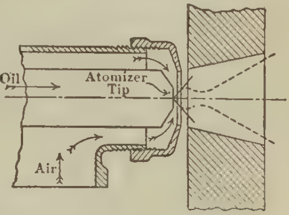

Fig. 7. Fan-blast Oil Burner

Steam atomizers use $^1/_3$ lb. to 1 lb. of steam per pound of oil; high-pressure burners using air require 10% to 15% of the total combustion air to be supplied under pressure; low-pressure burners require 30% to 50% to be supplied by the fan. In fan-blast burners, from 70% to 100% of the air is supplied by the fan.

For use with preheated air, the oil tube must be surrounded by a space through which cold air flows (as at 2 in Fig. 8); otherwise, carbonization and coke deposition will occur. Even with cold air, this takes place if oil is allowed to stand in the tip when the burner is shut down but exposed to radiation from the hot furnace interior. When shutting down a burner, all remaining oil should be blown out of it by air under pressure. The burner of Fig. 6*a* is designed also for preheated air.

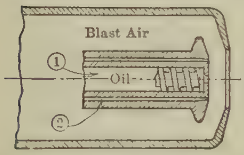

Fig. 8. Atomizing Tip

The proportions of the opening in the burner block are important for satisfactory operation. The opening should be conical or flared, diverging from the burner toward the furnace interior with a total included angle of 15 deg. to 35 deg. For cold air, the diameter, in inches, at the small end should be 1.0 to 1.3 × $\sqrt{\text{gallons per hour burned}}$. If the air is preheated, the diameter should be 40% to 50% larger. The length of the cone should be usually not less than 1 $^3/_4$ times the smallest diameter.

Where there is no opening around the burner, a hole should be provided in the furnace wall for observing the flame and for inserting oily waste when lighting. Blowing-out of the flame due to pulsations, or difficulty in lighting, may be obviated by providing a refractory tip extending into the flame path at the large end of the burner-block opening, or by setting a piece of firebrick in the opening so that the flame plays upon it.

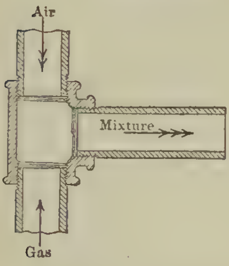

Fig. 9. Tee-mixing Burner for Gas

Up to about 1930, it was impossible to burn heavy oil satisfactorily in furnaces with many small burners and to produce consistently a product equal to that obtained with gas firing. This was because silt and other foreign matter in the oil clogged the small openings in the burners, and even with constant attention, produced constant fluctuations in furnace temperature and atmosphere. Improvements in oil filters have made it possible to obviate this difficulty, and with light oil as fuel and provision for preventing carbon deposits, results practically equal to heating with gas are obtained.

**GAS BURNERS.**—The functions which gas burners should perform are: Proportioning the gas and air; producing sufficiently rapid, but not too rapid, mixing; and giving direction to the flame. In only a few types is the proportioning effected satisfactorily over any considerable range of turn-down, unless special equipment is used, such as interconnected flow meters.

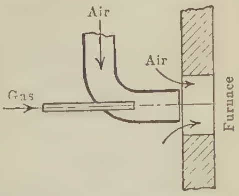

Fig. 10. Burner with Gas and Part of Air under Pressure

The simplest form of gas burner is the tee-mixer, Fig. 9. Proportioning requires the adjustment of two valves, one in the air pipe and one in the gas pipe. Sometimes the valves are mechanically interconnected. The completeness of mixing (which controls luminosity of flame and speed of combustion) cannot be varied. In the burner of Fig. 10,

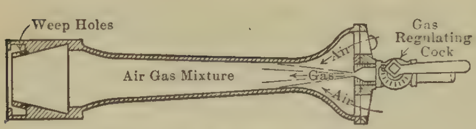

Fig. 11. Inspirator Gas Burner

however, this can be done by moving the gas pipe in or out with reference to the furnace wall, and to some extent by varying the opening between the tube and the wall. Both of these burners have a wide turndown range without danger of backfiring. Other advantages are simplicity, and wide range of adjustment of furnace atmosphere.

A widely-used type is the inspirator burner. One form is shown in Fig. 11. In this form, called the high-pressure type, the gas under pressure induces air from the atmosphere. In another form, the low-pressure type, air is supplied from a fan or blower under a small amount of pressure, and induces the gas which is maintained at atmospheric pressure by a reducing valve or regulator. The inspirator burner has the advantage of maintaining a practically constant gas-to-air ratio over a considerable range. If turned down to (usually) about 1/3 or 1/4 of its maximum capacity, backfiring occurs. The air-to-fuel ratio is quite sensitive to variations in furnace pressure. The inspirator burner produces almost perfect mixing and rapid combustion, with a very hot, nearly non-luminous "Bunsen" flame, which is an advantage in some cases, but a disadvantage in others. Several manufacturers now make good inspirator burners.

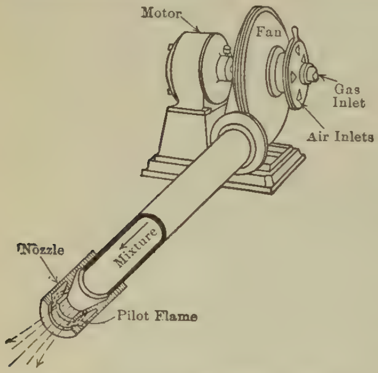

Fig. 12. Pre-mix Fan and Burner

The high-pressure type of burner has the advantage of requiring only one pipe and one fluid under pressure; it is, therefore, especially suited for installations having many small furnaces. No fan is needed, and adjustment is effected by a single valve burner. For city gas, or gases of lower calorific value, it can induce enough air without difficulty. For natural gas, the gas pressure must be quite high (in some cases up to 30 lb. per sq. in.) in order to induce the 10 or 11 volumes of air required per volume of gas. The high-pressure inspirator is more sensitive to change of furnace pressure than is the low-pressure type, is noisy in operation, and does not permit adjustment of the flame length. Inspirator burners have not been used with preheated air in the U. S., because of the danger of explosions.

In another system, the gas is mixed with about 1/4 of the total quantity of air required, put under pressure by a rotary blower, and passed to inspirator burners wherein it induces the remainder of the air required for combustion. The mixture in the blower and pipes is non-explosive. Pressure regulators are used to maintain the correct proportions of air to gas.

In the "pre-mix" burner, both air and gas are sucked into the inlet of a fan, mixed therein and supplied through a pipe to the burner nozzle. See Fig. 12. The nozzle has small holes for maintaining a pilot flame and preventing the flame from blowing away from the nozzle. The proportioning can be changed by moving the air shutter. The pre-mix burner also gives a Bunsen flame, although some luminosity can be produced by supplying only part of the air through the fan and inducing the rest around the nozzle. The danger of backfiring is even greater than with the inspirator burner, and explosion flaps or safety discs must be provided in the pipe line to prevent serious accidents.

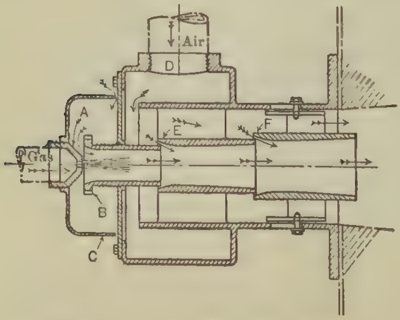

Fig. 13. Luminous Flame Burner

Luminous flames (such as are produced by the so-called diffusion burners) transmit heat more rapidly than do non-luminous gases, and they also reduce scaling of metallic objects being heated, by maintaining a reducing furnace atmosphere. An example of a luminous-flame burner is shown in Fig. 13. Gas under pressure issues from nozzle or "spud" *A*, while air from a fan enters at *D*.

A part of the air is induced into tube *E*, another part into *F*, and the rest flows outside of tube *F*. When cap *C* is screwed to the left, some air from the atmosphere is induced into tube *B*. The positions of tubes *B* and *F* are adjustable, while *E* is stationary. When *B* and *F* are moved closer to *E*, most of the air passes outside of *F*, and the flame becomes long and luminous. When *B* and *F* are moved away from *E*, the flame becomes shorter and less luminous. The turn-down range is 20 to 1.

Raw producer gas, because of the tar and soot which it contains, is difficult to handle in ordinary burners, and usually is sent into the furnace through openings in the firebrick wall. A special burner designed for producer gas is shown in Fig. 14. Air at about 1 lb. pressure induces the gas into the throat of the ignition tube, effecting excellent mixing. The relative proportions of the mixing and inducing actions can be varied by turning the handle at the back. The valve is designed to insure ease of opening even when stuck shut by tar deposits.

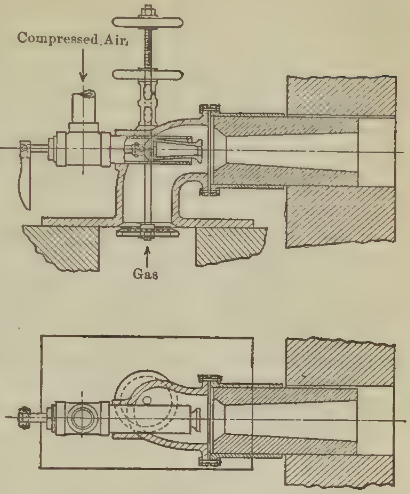

Fig. 14. Burner for Producer Gas

## 4. SELECTION OF FURNACES

**TYPES OF FURNACES.**—The type of furnace which is best adapted to carry out a given heating operation depends on many factors, as: Shape and weight of stock; number of times the process is to be repeated (job shop, or manufacturing establishment); cycle of heating (and cooling); highest temperature; uniformity requirements for heating; fuel which is available; capital which is available for investment. There are between 90 and 100 different types of furnace in use.

For general blacksmith work, the blacksmith's coal or coke fire is still found; more often gas- or oil-heated furnaces or fires as shown in Figs. 15, 16 and 17 are preferred. For more special work the types shown in Figs. 18 or 19 are common. Coal-fired heating furnaces for general forge work are built as in Fig. 20 with an end slot, or else with a side door. Heat-treating furnaces often are under-fired, for the sake of having a hot hearth, as in

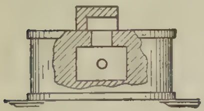

Fig. 15

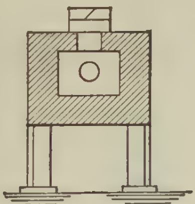

Fig. 16

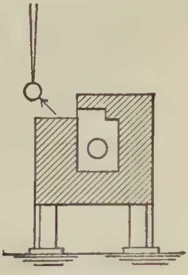

Fig. 17

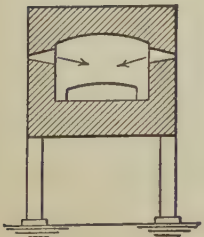

Fig. 18

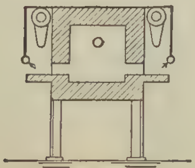

Fig. 19

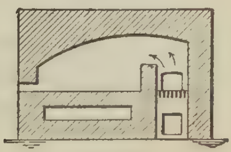

Fig. 20

Fig. 21. Pack hardening (carburizing) furnaces often are made under-fired (Fig. 22) with perforated hearth to secure uniformity of temperature. Tool-hardening furnaces usually have a preheating chamber above the main heating chamber, Fig. 23. Furnaces for heavy material are made of the car type, either side-fired as in Fig. 24, or over-fired as in Fig. 25. The side-fired type can carry a higher temperature than the over-fired type, which latter is commonly used for annealing or for heat treating. The car type has a cold hearth, hence the charge must be blocked up. Automatic conveyor furnaces, Fig. 26, are used for quantity heating of light material. The same is true of revolving-drum furnaces, Fig. 27, which also are used for gas carburizing. Bright annealing furnaces, Fig. 28, are used to anneal copper or similar material in a neutral atmosphere

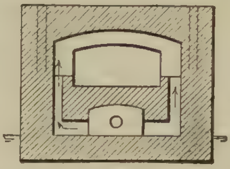

Fig. 21

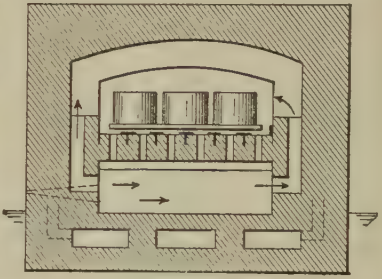

Fig. 22

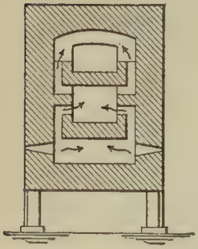

Fig. 23

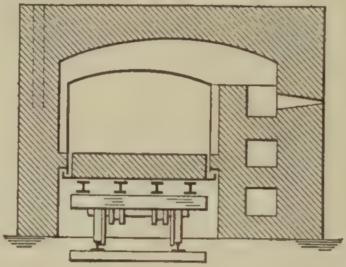

Fig. 24

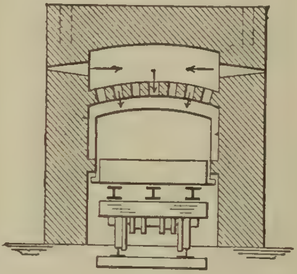

Fig. 25

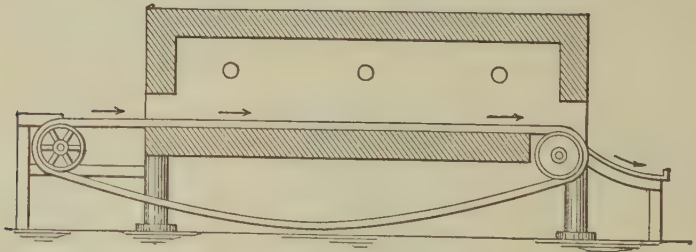

Fig. 26

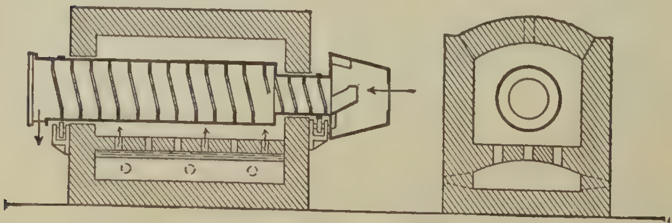

Fig. 27 Rotary Cylindrical Furnace

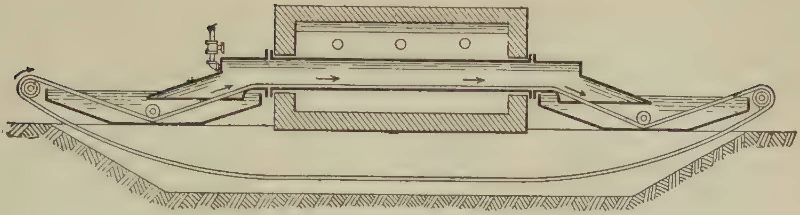

Fig. 28. Bright Annealing Furnace

Elevator-type furnaces, Fig. 29, are used for annealing; they avoid air leakage and oxidation. A portable type of furnace is the self-heated annealing cover, Fig. 30, in which combustion occurs within the tubes and the latter radiate heat to the charge. Tubes sometimes are placed under the top of the cover as well as at the sides. In operation, the material to be annealed is placed on the bottom part, which is separate from the cover; the latter is lifted by a crane and placed over the charge, fitting into a seal at the edges of the bottom part. In many cases, the air is drawn out and the interior filled with inert gases to prevent oxidation.

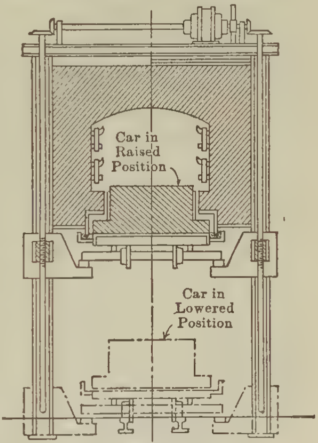

Fig. 29. Elevator Type Furnace

The bell-type electric furnace, Fig. 31, operates on the same principle, but is used for annealing coiled strip or wire. The "retort" or bell has a well in the center into which the central heating element, attached to the cover, fits when the cover is set in place. Inert gas is admitted into the retort through the pipe shown at the bottom. In larger furnaces of this type, a motor-driven fan is provided inside the retort at the bottom, for circulating the inert gas and effecting rapid cooling after the cover has been removed.

Pit furnaces, Fig. 32, are used for hardening large dies and long shafts. Rotating hearth furnaces, Fig. 33, are used to handle material which cannot be well moved through a furnace on chains or by pushers. Intermittent-conveyor, or rocker-bar, furnaces, Fig. 34, serve the same purpose. Their maintenance is difficult. Cyanide bath furnaces are very common for hardening. Pot furnaces, Fig. 35, heated either electrically or by flame, are used as lead baths or salt baths for heat treating to prevent oxidation; or with compounds containing sodium cyanide and other salts for liquid carburizing. Cyanide fumes are very poisonous, and hoods with stacks must be provided to carry them out of the furnace-room. In electrically-heated salt baths, the salt itself acts as the resistor in which the heat is

developed; current flows either from one electrode to the pot, or between two electrodes which dip into the bath. In the latter design, the current produces a circulating motion of the molten salt, which helps to maintain uniformity of temperature.

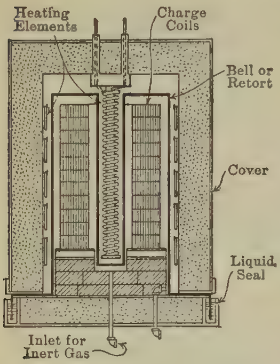

FIG. 31. Bell Type Furnace

Another type of furnace, much used for the heat-treating of many small pieces, is the convection-type furnace. One design is shown in Fig. 36. In this, heating is effected entirely by convection, by drawing the heated air through the charge. The convection furnace also may be fuel-fired, and combustion products or inert gases may be circulated instead of air. Close temperature control is obtained. High-temperature furnaces usually are unsuitable for low-temperature work, and *vice versa*, but a combination furnace has been designed in which high-temperature heating (up to 2400° F.) is effected, chiefly by radiation, while by re-circulating the gases, low-temperature heating (below 1200° F. with accurate control) is effected by convection.

**ELECTRIC FURNACES.**—Electric furnaces are so different from the usual combustion types that building them in the shop with the aid of an ordinary bricklayer seldom is attempted. With very few exceptions, they are purchased complete from manufacturers specializing in this work. For that reason, details of heating elements are not given here. Electric furnaces with resistors of nickel-chromium-iron or nickel-chromium alloy are excellent for heat-treating at 1200° to 1400° F., and for annealing at 1600° F. Above 1800° F. furnace temperature, such resistors burn out in short order. For forging (2200° F.) or for hardening high-speed steel (up to 2400° F.), bars of silicon-carbide or special alloys must be used as resistors. Two of these special alloys are: Kanthal, which contains up to 14% aluminum, up to 30% chromium, up to 6%

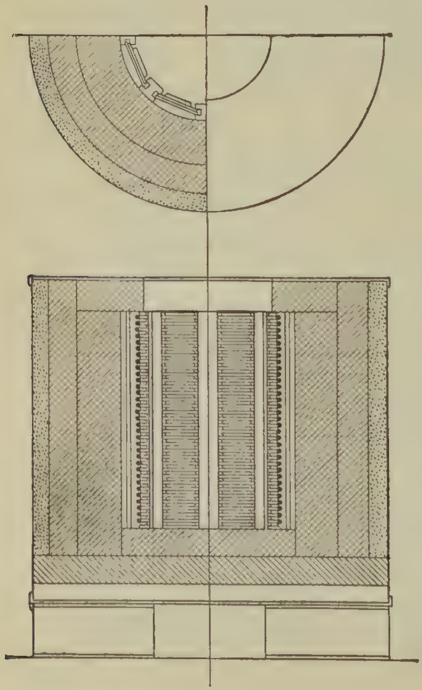

FIG. 32

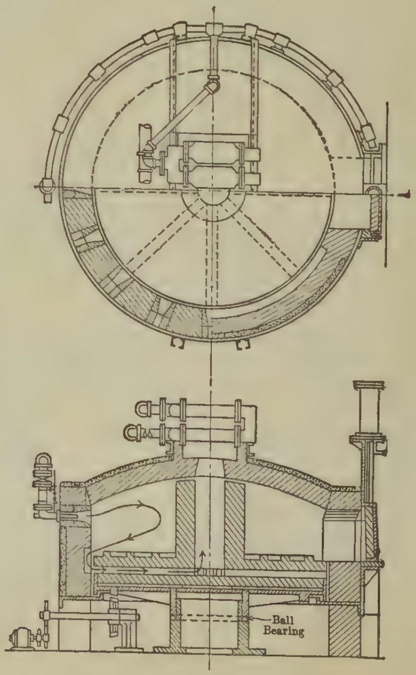

FIG. 33. Rotating Hearth Furnace

cobalt, and the remainder iron; Smith No. 10 alloy, which contains 37 $^{1}/_{2}$% chromium, 7 $^{1}/_{2}$% aluminum, and the remainder iron.

A resistor brought out in 1924, consisting of a metallic core imbedded in a ceramic material, did not prove successful, because at high temperatures the metal slowly vaporized and escaped through the porous ceramic material. However, a newly introduced composite resistor, called Stratite, is claimed to operate at 3000° F. over long periods. It consists of a core of molybdenum, surrounded by oxides which are not reduced by the action of the metallic vapor, the whole being cased in a material which becomes glass-like at high temperatures and prevents escape of the metallic vapor.

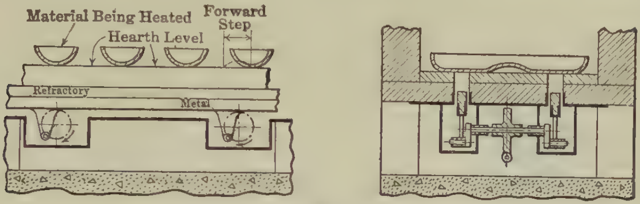

Fig. 34. Intermittent Conveyor Furnace

The silicon-carbide heating elements are almost unlimited as to temperature, but they gradually increase in resistance, to the extent of 30% to 80% after 400 hours operation. The expansion of the silica formed by internal oxidation produces a sudden increase of resistance when heating up from cold, which makes the oxidized bars practically unusable unless the furnace is maintained continuously at a temperature above 600° F. It is claimed that improvements in manufacture have eliminated this difficulty in 1936, and the bars last much longer. The difficulties in manufacture of the high-temperature alloy resistors have not been entirely overcome.

Because there are no products of combustion, the electric furnace eliminates the stack loss. On the other hand, heat is lost in the terminals, which must pass through the walls. If the terminals are made large in diameter, the conduction loss is great; if they are made small, heat is developed in and lost from the terminals themselves, with consequent danger of burning out. An advantage of the electric furnace is that heat can be developed in the hearth, insuring uniform heating throughout the charge.

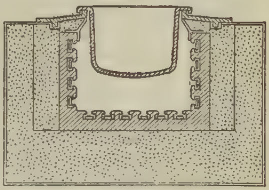

Fig. 35. Lead Pot Furnace

Electric heating can be effected without a furnace enclosure, as in the machines for heating rivets, or for heating bars for forging or upsetting. A heavy current at low voltage is passed through the bar between electrodes which grip the ends, or one end and an intermediate area, the bar acting as resistor. The process is to some extent self-regulating because of the radiation and the rapid increase of resistance of iron with temperature. Heating also can be effected by induction, as in a machine for hardening the bearing surface of automobile crankshafts, wherein a high-frequency, low-voltage current is passed through inductor blocks which closely surround but do not actually touch the bearing surfaces. The current thereby induced in the surface layer of the metal rapidly heats it to the required temperature; the current then is shut off and the heated surface is quenched by a spray from a water jacket within the inductor block. See pp. 18–22 to 18–28 for additional data on electric furnaces.

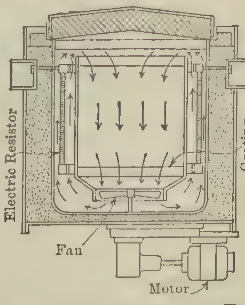

Fig. 36. Convection Type Electric Furnace

**CONVEYING OR MATERIAL HANDLING MEANS.**—Saving of labor is an important advantage of the continuous furnace in which the material to be heated is conveyed through the furnace by mechanical means. The suitability of the various conveying devices depends largely on the temperature. Up to 1200° or even 1400° F., the chain conveyor (Fig. 26) with solid links or woven wire mesh is satisfactory. Above this, and up to 1800° F., the rocker-bar (Fig. 34) or roller-hearth conveyors are suitable; the drum-type furnace also may be used for handling small pieces. For 2100° F. or over, the material either must be picked up and set down by tongs or charging machines intermittently inserted into the furnace, or must be pushed over the hearth. (See Trinks, Industrial Furnaces, Vol. II.)

**TEMPERATURE CONTROL.**—Automatic devices often are installed for controlling the furnace temperature; usually for keeping it constant, but occasionally for varying it with time according to a set program. The measuring device (see Governing, Regulation and Control, p. 10–03) usually is a thermocouple, which actuates the pointer of a depressor-bar millivoltmeter. When the pointer deviates from the desired temperature, contact is made to actuate a relay and contactors which, in electric furnaces, throw resistors into or out of circuit; or in fuel-fired furnaces operate a motor or solenoid to open or close the fuel and air valves as required. One form of temperature regulator uses air from a blower as the motive power, and thus avoids the use of solenoids.

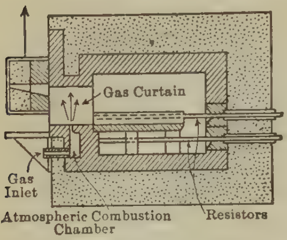

Fig. 37. Tool Hardening Furnace with Gas Curtain

The objections to present temperature-controllers for small furnaces are the first cost, the upkeep cost (especially in high-temperature furnaces), and the supervision which they require. If an inexpensive but rugged controlling device could be put on the market, many more furnaces would be automatically controlled than at present.

In low-temperature furnaces or ovens, gas or vapor thermometers or bi-metallic thermostats are used. With the thermometers, the ordinary contact type of instrument is used for simplicity, instead of the depressor-bar type. In automatic control of oil-burning furnaces operating above 800° F., the fuel and air never are shut off entirely, because the oil remaining in the burner tip would coke, and clog the opening. "All-on or all-off" control in this case means maximum-minimum control. Recently, proportional or "anticipating" controllers have been put on the market, in which the fuel and air supply is gradually adjusted over the range between the minimum and maximum.

**CONTROLLED ATMOSPHERE IN FURNACES.**—Oxidation or scaling of ferrous metals while being heated occurs if an atmosphere of air, carbon dioxide, or water vapor exists in the furnace, and to an even greater extent if actual combustion takes place in the gases in contact with the metal. The scaling grows rapidly with the temperature. It can be reduced or practically avoided by maintaining in the furnace a reducing atmosphere containing either a considerable amount of carbon monoxide (at least 8% is required for entire prevention of scaling), or a haze of carbon particles produced by cracking hydrocarbons. The former requires merely an excess of fuel. In direct-fired furnaces using natural gas, coke-oven gas, or coal gas, luminous-flame burners may be used to envelop the charge on the hearth in a blanket of fuel gas, which cracks and forms carbon particles; or secondary combustion devices, or "smoke burners" may be provided. In electric furnaces or muffle furnaces, a non-oxidizing atmosphere may be formed by supplying either hydrogen or the products of thermal decomposition of ammonia, or of natural gas, city gas, butane, or propane. These gases may be decomposed (the heat being applied by partial combustion) in a separate producer, or in the furnace itself. In small electric furnaces for tool hardening and similar work, where the door must remain partly open most of the time, a non-oxidizing atmosphere is maintained in the furnace by providing in front of the door a gas-flame curtain, as shown in Fig. 37. The oxygen in any air which succeeds in entering at the door is taken up by the gas, and an atmosphere containing CO and hydrogen, and sometimes free carbon and undecomposed hydrocarbons, is formed.

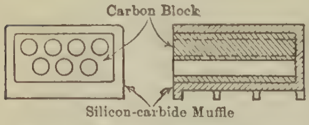

Fig. 38. Electric Furnace Muffle

For annealing copper or brass, an atmosphere of steam is used in furnaces such as those in Figs. 28 and 29. For heating high-carbon steel parts, such as tools, the atmosphere may be made not only non-scaling but non-decarburizing. An example is the electric-furnace muffle shown in Fig. 38, which consists of a hollow carbon block. Any oxygen entering at the open end reacts with the glowing carbon to form CO in high concentration. For brazing, an atmosphere of hydrogen is used; the parts are clamped together, coated with a paint containing finely divided copper or brass, treated with a flux, and placed in the brazing furnace in a hydrogen atmosphere. The copper is drawn between the contact surfaces by capillary attraction. Instead of the copper paint, a wire of special oxygen-free copper sometimes is used.

In addition to those mentioned, atmospheres of other gases are used for special purposes. For nitriding, the atmosphere consists of ammonia; for Chapmanizing, the ammonia is bubbled through a molten salt bath in which the pieces are immersed. For gas carburizing, a carbon-rich gas, *e.g.*, propane, is introduced into the furnace muffle; and in a recent development, carburizing and nitriding are combined by using a mixture of hydrocarbon gas and ammonia. A carburizing atmosphere also may be produced by allowing liquid hydrocarbons to drip slowly into the furnace from above.

Some of the devices used for maintaining a constant composition of furnace atmosphere by keeping constant the ratio of fuel to air, regardless of changes in the fuel rate, are: Interconnected fuel and air valves (only effective when both fuel pressure and air pressure are kept constant); positive blowers or fan blowers with proportioning mixers; inspirating burners (Fig. 11), in which the velocity of the gas is used to produce a suction which induces an approximately proportional amount of air, or *vice versa*; interconnected pressure-difference meters in the fuel and air lines, arranged to vary the air supply to maintain a constant fuel-to-air ratio. (Trinks, Industrial Furnaces, Vol. II, Chap. 4.)

**HEAT-SAVING DEVICES.**—In combustion furnaces of the batch type the products of combustion leave at high temperature and carry with them a large amount of heat which cannot be utilized directly in the furnace. A part of this heat may be recovered either by preheating the cold stock or by preheating the combustion air. Fig. 39 shows a furnace for preheating cold stock. The combustion air may be preheated either by a recuperator or a regenerator. In the recuperator the outgoing flue gases transfer a portion of their heat to the incoming air in a steady flow through a wall. In a regenerator the products of combustion impart heat to brickwork in a regenerator chamber, while the incoming air absorbs heat from the brickwork of another regenerator chamber which previously has been heated by the flue gases. The hot gases are caused to flow through first one and then the other regenerator chambers at regular intervals. The calculation of regenerative and recuperative surface is too long and tedious to be given here. For details of these calculations, see Trinks, Industrial Furnaces, Vol. I.

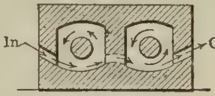

FIG. 39

For small, intermittently operated furnaces, it seldom pays to use heat-saving devices. Their proper field is in large, continuously-operated furnaces, especially in regions where fuel is expensive.

**EXAMPLE OF FURNACE CALCULATION.**—Furnace for heat-treating small steel parts, at the rate of 500 lb. per hour. Furnace is of the under-fired type, Fig. 21. Temperature of furnace = 1450° F. From Fig. 1, increase of heat content from 60° F. to 1450° F. = (222 − 6) = 216 B.t.u. per lb. For steel, the heat content is actually slightly higher than this value, which applies to pure iron. From Table 2, the thermal efficiency of the given type of furnace under average conditions = 19%. Heat required in fuel per pound of steel = 216/0.19 = 1140 B.t.u. If the fuel to be used is oil of 140,000 B.t.u. per gal., the fuel consumption is (500 × 1140)/140,000 = 4.1 gal. per hour.

From Rule 3, p. 18–05, the rate of heating will be about 30 lb. per hour per sq. ft. of hearth. Required area of hearth = 500/30 = 16.7 ft. The shape of the hearth and height of the heating chamber are determined by the size of the pieces and the method of charging, or in some cases by the nearest standard sizes of the furnace builders.

Taking rate of heat liberation by combustion as 12 B.t.u. per cu. ft. per second, the volume of combustion space required is (500 × 1140) ÷ (3600 × 12) = 13.2 cu. ft. The height of chamber required to give this volume of combustion space depends upon the shape and size of hearth supports, but would approximate 15 in. The rate of 12 B.t.u. per cu. ft. per sec. is somewhat high for the combustion of fuel oil with burners of the usual type, but this simply means that part of the combustion takes place in the upper or heating chamber. No harm is caused thereby.

From the table of flue sizes (see p. 18–06), area of flue openings required for furnace temperature of 1400° F. = 2.0 sq. in. per sq. ft. of hearth; for 1450° F. furnace temperature it would be somewhat more, or about 2.5 sq. in. Hence, 2.5 × 16.7 = 42 sq. in., total area of flues. The flue dimensions are made multiples of 2 1/2 in. and 4 1/2 in.

The size of doors is determined by the size and shape of heating stock and the method of charging.

# INDUSTRIAL ELECTRIC HEATING

By R. M. Cherry

## 1. FIELD AND CLASSIFICATION

Electric heat may replace advantageously fuel and steam in many industrial heating processes, because the heat generated by electricity usually can be applied at a higher efficiency than is realized with fuel. Its application for heating often results in increased production, a better quality of work, and in many cases lower overall costs.

Whether or not electric heating is used for a given application depends on the complete cost analysis, including such factors as cost of heat, quality of product, labor of attendants, subsequent operations, working conditions, complaints, rejects, etc.

Industrial electric heating gives perfect heat distribution, and permits great flexibility in temperature control. Automatic control is recommended for practically all applications, as it not only gives better control of temperature and heat distribution, but also eliminates the labor of attendants, danger of spoilage, and insures that parts subjected to heat receive exactly the same treatment, thereby producing uniform results.

In general, industrial electric heating is classified as:

1. Small heating units and devices, for such applications as small ovens, heating watchmen's houses, crane cabs, soft metal melting pots, liquid heating, glue pots, process machinery, etc.
2. Ovens for baking, drying, etc.
3. Resistance furnaces, for heat-treating metals, porcelain enameling, etc.
4. Melting furnaces for melting steel, copper and brass.
5. Inductive heating of metals.

## 2. SMALL HEATING UNITS AND DEVICES

Manufacturers' catalogs contains fairly complete information on small heating units and devices, method of application, and determination of type, size and rating of the units required for a particular service.

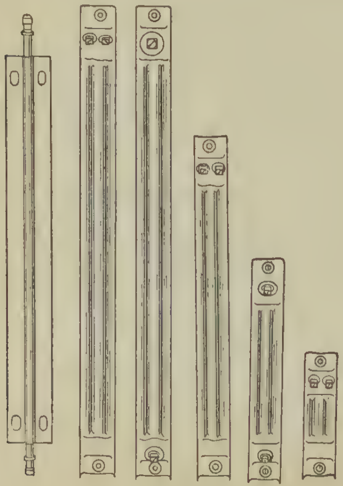

Fig. 1. Strip Heaters

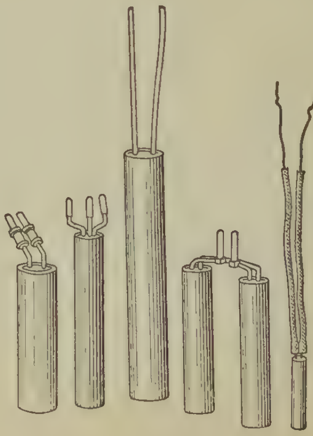

Fig. 2. Cartridge Units

Small heating units and devices are, in general, classified as: Air heating, liquid heating, and contact heating. For these applications, there are various types, sizes and ratings of standard heaters, generally known as strip heaters, tubular type heaters, and cartridge heaters.

**STRIP HEATERS** are used principally for air heating and contact heating. They consist of an outer metal sheath with the coiled resistance wire electrically insulated from the outer sheath and provided with suitable terminals. These heaters are usually approximately 1 1/2 in. wide, 1/2 in. thick or less, and available in standard lengths from approximately 7 in. up to 4 ft. They are used principally for heating watchmen's houses, crane cabs, valve houses, isolated rooms, small ovens, pump houses, ticket booths, process machinery, etc.

**TUBULAR-TYPE HEATERS** are used principally for liquid heating and contact heating. They comprise a tubular outer metal sheath in which the resistance wire, electrically insulated from the outer sheath, is coiled. The outer sheath material may be steel, nickel, copper, stainless steel, Monel metal, etc., depending on the application of the unit. This type of unit can be formed into almost any desired shape. Also, it may be cast into gray iron, alloy iron, aluminum, or other metals. Such cast-in units provide a large area in contact with the liquid to be heated, and form a mechanically strong unit.

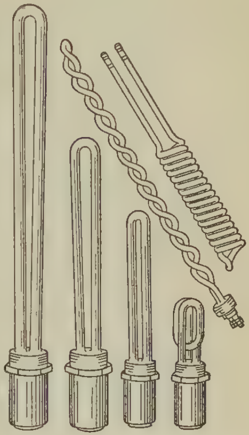

FIG. 3. Immersion Heating Units

Tubular units, either of the plain sheath type or cast-in type, are used principally for heating such liquids as water, oils, paraffin, alkaline baths, nickel-, copper- or chrome-plating bath solutions, mild sulphuric acid solutions up to 10% concentration, if no other acids are present; for melting soft metals, as tin, lead, solder, babbitt, type metal, and similar alloys; and for heating salt baths to temperatures up to approximately 1000° F. Locating the heating units directly in the liquid to be heated, gives a maximum efficiency of heating, in that all of the heat is generated in the liquid itself; also, this method of applying heat provides for the best possible temperature control.

The tubular type heating unit is made in sizes varying from approximately 1/4 to 3/4 in. diameter and from 2 to 20 ft. long. The size and rating depend on the application.

**CARTRIDGE HEATERS.**—Cartridge heating units are used principally for contact heating. The construction is similar to that of the tubular unit, in that it consists of an outer shell of metal, and coiled resistance wire suitably insulated from the outer shell. The two terminals of the heating unit are brought out at one end. Cartridge heaters are used where small quantities of heat are required at a definite location. They are applied usually by drilling a hole in the part to be heated and inserting the heating unit.

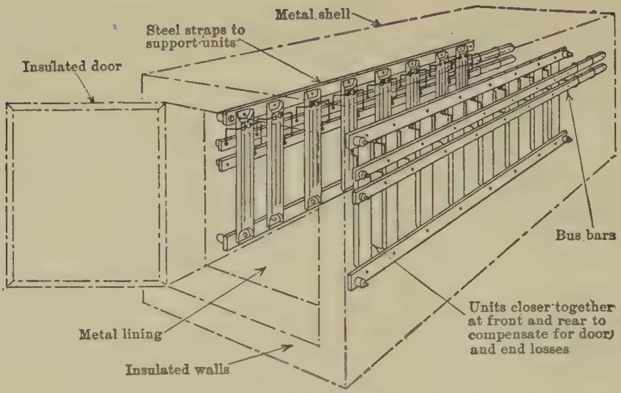
Cartridge heating units are available in sizes from 3/8 in. outside diameter by 1 1/2 in. long to approximately 1 1/4 in. outside diameter by 8 1/2 in. long. Ratings range from 50 watts in the smaller size, up to approximately 1200 watts in the larger size. These ratings are based on a sheath material of brass. Cartridge heating units also are available with an alloy steel sheath, suitable for a maximum sheath temperature of 1200° F. The electrical rating for these units is approximately 50% higher than those listed above.

Typical heaters are shown in Figs. 1, 2 and 3. Fig. 1 shows several forms of strip heaters, and Fig. 2 various arrangements of cartridge heaters. Fig. 3 illustrates a number of varieties of liquid heating units, technically known as immersion units. As shown, the units may terminate in a pipe fitting which may be screwed into the wall of the chamber containing the fluid to be heated. Typical methods of application of the strip, tubular and cartridge units are shown in Figs. 4, 5 and 6.

## 3. OVENS FOR BAKING AND DRYING

Electric ovens are widely used for many industrial applications. Examples are core baking, paint drying, japanning, bread and cake baking, and baking of such electrical parts as armatures and coils.

**Batch-type Ovens** are used principally for small production. A typical batch oven is the box type, with a door at one or both ends. The material to be baked is loaded on trays, trucks, or an overhead intermittently-operated conveyor.



Metal shell
Steel straps to support units
Insulated door
Bus bars
Units closer together at front and rear to compensate for door and end losses
Metal lining
Insulated walls

FIG. 4. Strip Heaters Mounted in a Small Oven

**Continuous Ovens** are used for quantity production. Typical continuous ovens are the straight-through conveyor type, straight-through conveyor oven with ventilating air passing counterflow to the work, or continuous counterflow oven where outgoing hot material preheats incoming cold work.

The electrical equipment for such ovens consists of standard type oven heaters and suitable automatic control equipment. The heaters usually are open-type ribbon resistors, wound on suitable insulators. These, in turn, are supported in a metal frame, suitable for mounting on the walls or floor of the oven. A typical installation of strip heaters is shown in Fig. 4.

**VENTILATION** is an important factor for many oven applications, such as those used for paint drying and japanning, where considerable quantities of volatiles are given off during heating. The amount of ventilation required depends on the size of oven, the size and surface area of parts being baked, and the amount of volatiles to be driven off. Most of the volatiles are driven off during the first part of the heating cycle. Therefore, in a continuous oven they must be removed near the entrance to the oven. All dipped or sprayed parts should be allowed to drip thoroughly before being placed in the oven.

**ENERGY REQUIRED** for the baking of particular parts depends on the production, and size and type of oven. The approximate energy required for various applications is as follows:

| Application.................... | Japanning | | Core Baking | | Bread Baking |
|---|---|---|---|---|---|
| Type of oven................. | Batch | Continuous | Batch | Continuous | Continuous |
| Approx. lb. per Kw.-hr......... | 15–20 | 25–45 | 10–12 | 12–15 | 10–12 |

## 4. RESISTANCE FURNACES

The resistance furnace consists of a heating chamber, containing heating units, which may be mounted on the side walls, roof, floor, doors, depending on the application. Heat is transmitted to the work by radiation and convection. Resistance furnaces are used for such heating applications as annealing, normalizing, hardening, drawing, carburizing, porcelain enameling and brazing.

**RESISTORS** are principally the metallic resistor in rod, ribbon or cast form, or a non-metallic resistor, as silicon carbide, usually in round bar form. Nickel-chromium alloy (approximately 80% Ni, 20% Cr) is universally used for operating temperatures up to a maximum of approximately 2100° F., which covers the majority of industrial heating applications. A metallic resistor material (an Al-Cr-Fe alloy) recently developed (1937) may increase the maximum temperature range of the metallic resistor.

**TYPES OF FURNACE.**—(See also pp. 18-13 to 18-18). Many standard types of furnace are available, the selection of type and size of furnace depending on the application, production, and method of handling desired. The more common types of furnaces are:

**Box-type Furnace,** which is essentially a box, with a door at one or both ends. The parts to be treated are handled by hand, either individually or in containers.

**Pit Furnace,** which may be either circular or rectangular, with the opening at the top, and provided with a suitable cover.

**Bell Furnace,** which may be either circular or rectangular. The material to be treated is loaded on bases, and the furnace is lifted and moved from base to base; or the furnace may be lifted and the bases moved. Bell furnaces are used either with or without an inner retort, depending on the application.

**Elevator Furnace,** which may be either rectangular or circular, usually rectangular. The work is loaded on a car, which is pushed under the furnace and elevated into the furnace chamber.

**Car-bottom Furnace,** which is similar to the box-type furnace, except that the hearth is mounted on wheels to permit it to be removed for loading and unloading.

**Pot Furnace,** which consists of an inner metallic pot, with the heating units located outside of the pot. Pot furnaces are used principally for lead hardening, cyanide or salt hardening, and hot dip galvanizing.

**Pusher Furnace,** in which the work is pushed through the furnace, one piece against the other where the parts can be so handled; or the parts are loaded on stools or trays, which are pushed through the furnace one position at a time.

**Rotary-hearth Furnace,** in which a rotating table, provided with sand seals between the rotating table and stationary part of the furnace, carries the parts to be treated. Loading and removal of work is through the same or adjacent doors, thereby providing for loading and unloading from one central point.

**Roller-hearth Furnaces** have a hearth of driven rolls, on which the material being treated is carried through the furnace. The spacing between rolls depends on the parts or trays to be handled. The rolls extend through the walls of the furnace to bearings mounted on the outside.

**Conveyor Furnaces** are of many types, depending on the type of conveyor used, as a mesh-belt, cast link belt, monorail conveyor, etc. For such applications as hardening of steel, the conveyor should be arranged to remain in the furnace at all times to conserve heat. When the furnace is used for annealing, the parts being cooled in the furnace, the conveyor usually returns underneath it.

**ATMOSPHERE EQUIPMENT FOR RESISTOR FURNACES.**—The trend in resistor furnace applications is the use of protective gas atmosphere in the heating and cooling chambers to prevent oxidation during the heating cycle. Typical applications are for bright annealing copper and steel, scale-free hardening, scale-free annealing of castings, electric furnace brazing, etc. For most of these applications, a suitable protective atmosphere is provided by equipment which processes the available gas, such as city gas, natural gas, butane, propane, etc.

An equipment for re-forming the available gas consists of suitable visual flowmeters to indicate the amount of air and gas used, a motor-driven air-gas mixer, a combustion chamber with burner, and a surface cooler for removing excess moisture. In operation, air and gas are fed into the combustion chamber at a definite ratio, which depends on the gas used and the required analysis of the output gas. In the combustion chamber, the gas is burned with a deficiency of air, in the presence of a catalyst under controlled conditions. The output gas contains principally nitrogen, hydrogen, carbon monoxide and carbon dioxide. The relative proportions of the constituent gases depend upon the air-gas ratio used.

The output gas may be purified, depending on the requirements of the application.

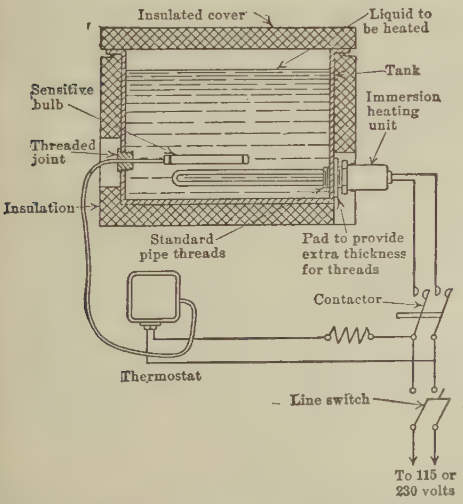


Fig. 5. Immersion Heater Applied to a Tank, Including Automatic Control Equipment

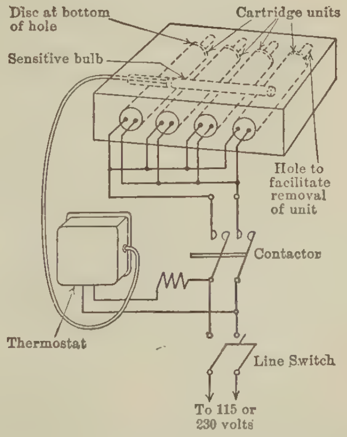

Fig. 6. Application of Cartridge Units with Automatic Temperature Control

For example, most city gases contain a small amount of sulphur, which must be removed if material such as copper is to be bright annealed. In other applications, it is essential to remove more of the moisture from the gas, either by refrigeration or chemical dryers, or both.

The cost of a protective atmosphere is relatively low. For instance, in bright annealing copper, and using available city gas of 530 B.t.u. content per cubic foot, the air-gas ratio used is approximately 4 : 1. Therefore, a gas output of 1000 cu. ft. would require approximately 250 cu. ft. of city gas. For scale-free hardening, the air-gas ratio may be approximately 2 1/2 : 1, and there would be required approximately 400 cu. ft. of city gas of 530 B.t.u., per 1000 cu. ft. of output gas.

When a higher reducing gas than that provided by processing available gases is desired, an ammonia dissociator may be used. The equipment is essentially a tube or coil, containing a catalyst, through which the ammonia gas passes, inserted in an electric furnace. The ammonia gas dissociates when heated to the required temperature, the resulting gas containing 75% hydrogen, 25% nitrogen. Many sizes of standard atmosphere equip-

**Table 1.—Typical Applications of Electric Resistance Furnaces**

ments are available for a wide range of outputs and applications. Makers should be consulted in regard to equipment for special conditions.

The quantity of atmosphere required depends on the type and size of furnace, and the application. In general, it is a relatively small item in the total cost. Such protective atmosphere easily can be supplied to practically all types of furnaces, if they are properly designed for use with protective atmosphere.

The protective atmosphere eliminates oxidation of most materials. A considerable saving is effected thereby, by the elimination of the subsequent cleaning operation, and the quality and appearance of the product is improved. The cost of fabrication, such as brazing fabricated metal parts in the electric furnace, is lowered.

**SELECTION OF TYPE. ENERGY REQUIRED.**—Table 1 gives, in general, the types of furnaces used for various applications. The type and size of furnace to be selected depend on the size, shape, weight and material of parts to be treated, as well as the production and the desired heating and cooling cycle. The energy required, usually stated in net pounds per kilowatt-hour, based on continuous operation, depends upon the size of furnace, production, and the heating cycle. The data in Table 1 are approximate and are to be used only as a rough guide.

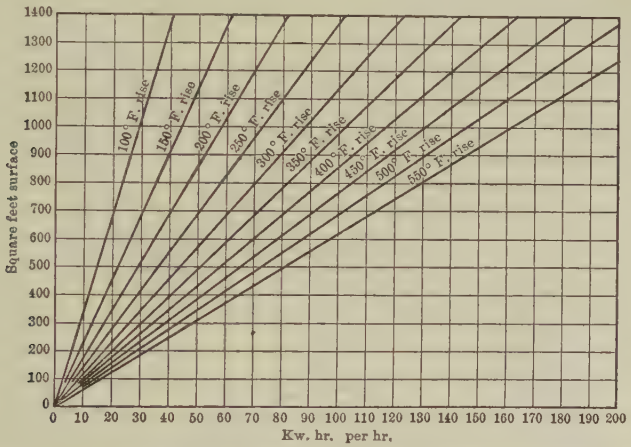

FIG. 7. Heat Loss Through 1-in. Thick Insulation of 85% Magnesia or Similar Insulator. Heat Loss Varies Inversely as Thickness

**ENERGY CONSUMPTION AND ELECTRICAL RATING.**—An estimate of the energy required for a given application should include the heat absorption of the material being heated, heat absorption of auxiliaries used for carrying the work, as trays, conveyor, etc., heat absorption of the ventilating air if used, heat absorption of the protective gas atmosphere if used, heat losses through the walls, doors, etc.

The heat absorption of the material to be heated, including the net work, conveyor, trays, etc., can be calculated by

$$\text{Kw.-hr.} = \{w \times h_s \times (t_2 - t_1)\}/3412,$$

where $w$ = weight of material being heated, $h_s$ = average specific heat, $t_1$ and $t_2$ = respectively, initial and final temperatures of the material, deg. F. Heat losses for many applications may be estimated by means of Figs. 7–11. The heat loss data in the above curves are principally for low temperature applications. For the higher temperature resistance-type furnaces, operating up to approximately 1850° F., a good rule-of-thumb method for estimating the heat loss in Kw.-hr. is

$$\text{Kw.-hr.} = (0.8\ A \times T)/10{,}000,$$

where $A$ = inside wall area of heating chamber, sq. ft. and $T$ = operating temperature, deg. F. The application of this rule will give the approximate heat losses through the insulated walls and closed doors, based on a well-insulated furnace.

**REFRACTORIES AND INSULATION FOR OVENS AND RESISTOR FURNACES.**—The usual construction of ovens, for temperatures up to approximately 600° F., comprises a metal inner liner and an outer shell, the space between being filled with insulating material, as 85% magnesia, rock wool, mineral wool, etc., care being used to have little or no through metal.

The thickness of insulation used depends on the operating temperature and, in general, should be at least as follows:

| | | | | |
|---|---|---|---|---|
| Oven temperature, deg. F. | 200 | 400 | 600 | 800 |
| Approx. thickness of insulation, in. | 2 | 4 | 5 | 6 |

For electric resistance furnaces, the wall construction consists of an inner refractory lining of brick, backed by a suitable thickness of insulating material. Several types of light-weight refractory are available in standard brick sizes. These bricks are of less than half the weight of regular firebrick, thereby providing for additional insulation, and absorbing less heat while the furnace is being heated to operating temperature. For the average size heating chamber, the inner refractory lining of 4 1/2-in. standard light-weight refractory brick is sufficient. For high walls and long spans for arches, this thickness should be increased. For data on refractory brick see pp. 5–03 to 5–20 of this book. For additional data on heat insulation see Kent's Mechanical Engineers' Handbook—Power, pp. 3–54 to 3–71, forming Vol. 2 of this series.

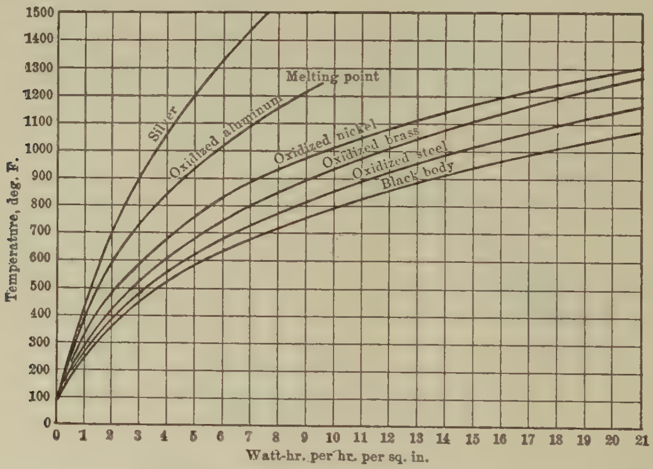

FIG. 8. Heat Losses from Various Metals

The thickness of insulation depends on the operating temperature and the complete time-temperature cycle. A furnace to be held at operating temperature for long periods should be well insulated. For a cycle requiring cooling of the charge in the furnace, the thickness of the insulation must be in accordance with required heating and cooling cycle.

In furnaces held at the operating temperature, the thickness of the insulation, in addition to the refractory lining, should be approximately as follows:

| | | | | |
|---|---|---|---|---|
| Operating temperature, deg. F. | 800–1100 | 1100–1400 | 1400–1800 | 1800–2100 |
| Approx. thickness of insulation, in. | 5 | 7 1/2 | 10 | 12 1/2 |

## 5. MELTING FURNACES

The three types of electric melting furnaces are, in general, the resistance furnace, arc furnace, and induction furnace.

**RESISTANCE FURNACES**, usually of the pot type, are used for melting soft metals, as tin, babbitt, lead, solder, type metal, etc. The heating units may be immersed directly in the metal to be melted, or placed outside of the melting crucible, depending on the application.

**ARC FURNACES**, in general, are of two types, the direct arc and the indirect arc.

**The Direct Arc Furnace** is used principally for melting and refining steel. The 3-phase arc furnace, generally used, has three electrodes. The electric current passes between the electrodes and the bath of metal. Each electrode is provided with a motor-driven mechanism which, by suitable automatic control, raises and lowers the electrodes to maintain a constant power input.

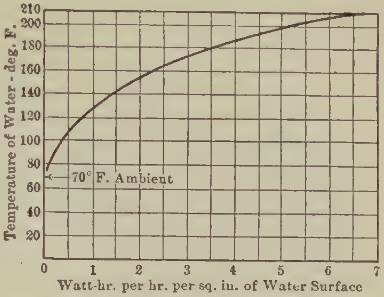

Fig. 9. Heat Losses from Open Water Surfaces

**The Indirect Arc Furnace** usually has two electrodes. The current passes between the electrodes and above the bath, which is heated by radiant heat from the electric arc, as well as by conduction and convection. This type of furnace is used frequently for melting of copper and brass.

**Electrical Equipment** of an electric arc furnace consists of a step-down transformer, primary and secondary control, motors for raising and lowering the electrodes, and a tilting motor if the furnace is to be of the tilting type. The primary control consists of an oil-circuit breaker on the high-voltage side of the step-down transformer, suitable means for changing taps on the transformer, and metering equipment. The secondary control consists of control equipment for controlling the movement of the electrodes to maintain constant power input. Voltages used on the arc vary, depending on the character of the application. The higher voltages are used normally for melting down, and the lower voltages for refining.

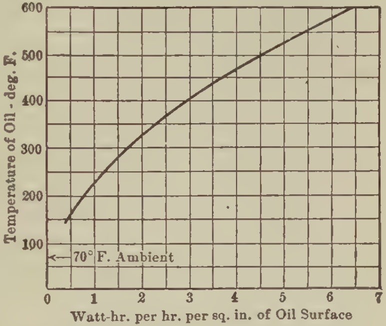

Fig. 10. Heat Losses from Surfaces of Oil Baths

**INDUCTION FURNACES** are of two types, the core type, used on standard frequencies, and the coreless or high-frequency furnace.

**Core-type Furnaces** consist essentially of an electrical transformer circuit with a primary coil, a laminated iron core, and the bath arranged for completion of the secondary circuit. Heating is accomplished by the induced current in the secondary. This type of induction furnace is used principally for melting brass and copper.

**Coreless or High-frequency** furnaces consist of a crucible to hold the material to be melted, around which is placed a water-cooled copper coil to which the high-frequency source is connected. Heat is generated by the electric current induced in the charge. The rate of heating is limited practically only by the capacity of the high-frequency source. This type of furnace provides for rapid heating, accurate control of heating, agitation of the bath, and is used principally for the melting of alloy steel.

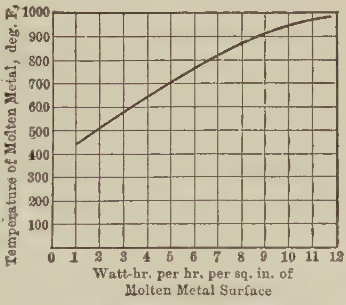

Fig. 11. Heat Losses from Surface of Molten Lead, Tin, Type Metal, Babbitt, etc.

**ENERGY REQUIRED FOR MELTING** in induction furnaces depends on the size of furnace, and the material to be melted. In general, the approximate electric energy consumption for melting for various applications is as follows:

| | |
|---|---|
| Brass, yellow (core induction furnace) | 220 to 350 Kw.-hr. per ton (2000 lb.) |
| Brass, red ( " " " ) | 250 to 400 " " " " |
| Copper (indirect arc furnace) | 250 to 400 " " " " |
| Steel (3-phase arc furnace melting only) | 450 to 600 " " " " |
| Steel (coreless induction furnace) | 500 to 800 " " " " |

The selection of the right type and size of furnace for a given application requires experience and, in some cases, tests. When there is any question as to size and type of furnace, manufacturers of such equipment should be consulted. Complete data should be given, *i.e.*, voltage, phase and frequency of the power circuit; floor space and head-room available; the size, shape and material of parts to be treated; the complete heating and cooling cycle desired; the efficiency of loading, *i.e.*, pounds of material to be loaded per square foot or cubic foot; production per given time, hours to be operated per day or week.

## 6. INDUCTIVE HEATING OF METALS

The use of high frequency (1000 to 3000 cycles) for heating (not melting) metals, for such application as skin hardening is of recent (1937) development. This method of heating permits heating only that portion of the metal that requires hardening. In addition it permits of heating only the surface of that portion. A typical example is the heating of the bearing surfaces of crank-shafts for hardening. A high-frequency current of low voltage and high amperage is passed through inductor blocks which surround but do not actually touch the area to be heated. The inductor block current induces a current in the surface of the metal, thereby providing quick heating of the outer surface.

This method of heating reduces the time for hardening of heavy parts, such as crank-shafts, from hours to seconds and gives a superior product at lower overall cost. High-frequency heating for surface hardening is particularly applicable to the heating of steel parts of cylindrical section.

# FORGING PRACTICE *

By Eugene C. Clarke

Forging, the plastic forming of hot metal, is one of the older arts of civilization. The early smiths provided the energy necessary to form the metal by striking with hammers the subject held in place on anvils. Also, they were the early heat treaters; they tempered their products.

The operations and mechanisms cited below account for the production of practically all the forged products in current use. There are, of course, special operations employing modifications or different applications of the principles described, but the tonnage so produced is relatively insignificant.

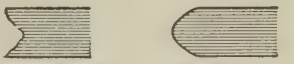
Progress in the reduction of the art of forging to a scientific basis has brought about specialized development of the various elements involved in shearing, heating, plastic formation, trimming, heat treating, sizing, inspecting, and the many other operations incident to modern practice. The plastic forming of the metal, being accomplished by working the metal beyond its elastic limit, has not enjoyed the same theoretical study that is common to processes within elastic limits, and practically all formulas employed are empirical.

**ENERGY REQUIRED.**—If in mechanical forging $E$ represents the forging energy, $V$ the velocity of impact of the forging element of a mechanism, and $W$ the weight or force applied, $E = WV^2/2g$. From this it is readily appreciated that the weight or pressure applied must be greater than the affected mass of the forging and that, with the size of the forging placing a practical limitation on mechanical equipment employed, the classes of forging equipment are economically complementary rather than competitive.

The rate of plastic flow of the subject metal at forging temperature limits the amount of deformation per operation and governs the application of forging power. If deformation is accomplished beyond the rate of plastic flow, rupture of the metal occurs. The rate of plastic flow varies with the subject material, its form and density, its temperature during the forging operation, and the velocity and continuity of power application.

**LIMITATIONS.**—This discussion is confined to consideration of actual forging applications. It, therefore, cannot include details of heating, shearing, heat treatment, etc., but a few characteristics of the metal being forged exert influences common to all procedures and are briefly mentioned.

During all forging operations the metal is cooling. Hence its fluidity for plastic flow is being reduced. The duration of any forging operation thus is limited, the limitation varying further with the kinds of metal being forged. The forging dies are extracting heat from the forging in relation to the time in contact with it. Hammer dies have relatively little thermal effect, but in press dies this extraction of heat is a major consideration.



Hammered Section (Exaggerated)
Pressed Section (Exaggerated)

Fig. 1. Metal Flow—Presses and Hammers

When the forging is larger in the area to be deformed than the impinging or contacting dies, as in cogging down an ingot, the forging effect is reduced by the resistance to distortion of that part of the metal not in contact with the dies of the forging mechanism. The deformation necessarily is limited in scope to that which will not cause laps at adjoining forged areas and which does not shear the metal at those sections under the edges of the dies.

When the forging is smaller in area than the die face, a limitation on height is introduced. Generally, the greater the area upon which the dies impinge, as related to the height between impinging dies, the less is the control of plastic deformation, with the limitation that the distance between the dies at the point of impact cannot safely be greater than three times the smaller sectional dimension. When the height limitation is exceeded the forging frequently will bend, forming a lap, rather than follow the desired plastic deformation. The hammer with high impact velocity is effective on thin stock which is unworkable in a press, and the press is more effective on relatively thick sections. The difference in metal flow under the two tools can be observed at the ends of sections reduced by forging. That reduced under a hammer will have the edges extending beyond the center; that reduced under a press will have the center extending beyond the edges.

---

* *Forging* as discussed herein is defined as the craft of the smith and as such does not consider plastic deformation as accomplished in rolling mills.

**IMPACT AND PRESSURE.**—The velocity, constancy and duration of the applied forging force are best considered with relation to the mechanism employed. The first application of force must overcome the initial resistance to deformation of the metal, after which plastic flow will occur only so long as the force is continued in motion and in magnitude. Coincident with the application of the force, the density of the metal is increased, increasing its resistance to flow. That immediately worked-on area of the metal in contact with the forging dies is further restricted by friction between die and work, and this increases with the magnitude of the force.

The mechanical application of power to accomplish plastic deformation or forging has been developed along two distinctive lines: 1. Impact forging, *i.e.*, the utilization of the energy due to velocity at impact as in hammers; 2. Pressure forging, *i.e.*, the application of pressure at relatively low velocity.

Tremendous strides have been made in mechanization of forging processes. Forging equipment generally divides into three groups, namely hammers, hydraulic presses, and crank-driven machines. Likewise forged products have developed along clearly defined lines, *i.e.*, drop forgings or die forgings, made within enclosing dies controlling form and size; drawn forgings combining piercing and extruding, as shell blanks; and, that group of forgings manipulated, between open dies, to form and size, and controlled by observation or gage.

**Forging by Impact,** as by hammers, is an application of maximum force during contact of dies and metal; the forging effect continues until the resistance to flow brings the impacting die to rest, thus absorbing all the useful energy of the applied force. If the hammer blows are of sufficient rapidity, advantage is gained of the momentum of flow, and greater rate of flow per blow is attained than will be the case with blows at greater intervals.

**Forging by Pressure,** applied and maintained in motion hydraulically, is limited by the resistance to flow of the metal, the increased density of the metal between the dies, the friction between dies and work and the increasing resistance to flow caused by reduction in temperature during the operation. Forging by pressure applied through a crank mechanism is the application of a force of increasing magnitude at decreasing velocity. Such applications are almost universally applied to forgings completely enclosed in dies; the limitations on useful deformation then are the amount of metal under compression in the dies, and its density as being workable within the useful force available.

**GRAIN FLOW.**—The strength and durability of steel forgings are at their maximum values only when the grain flow lines are in the correct position. The selection of the forging mechanism, the determination of the successive forging operations, and the design of dies are governed by the required grain flow. Grain flow in steel is the fibrous structure imparted to the constituents by mechanical working as in rolling or cogging. The alignment of such fibers is parallel, and in the longitudinal direction of the working.

Forging operations should dispose the grain flow to the best advantage of the duty of the finished forging. Thus gear blanks are upset to secure radial grain flow and uniform strength in all teeth. If the blank were forged with longitudinal grain flow, half the teeth would have cross grain flow, and thus would be weaker than the remainder.

In a crank-shaft, the grain is required to flow without rupture through the cheeks, pins and bearings, and to be radial at the end when a flange or disc is employed to transmit the power of the engine or motor of which the crank-shaft is a part. The size of the crank-shaft determines the equipment employed. An automotive crank is forged from rolled stock in a drop hammer, and the end is upset in a forging machine.

Table 1 shows the characteristics of impact forging and pressure forging, and illustrates the current uses and limitations of equipment available in 1937 markets.

## 1. IMPACT OR HAMMER FORGING

Impact forging is commercially developed along two lines: 1. *Drop-forging*, or *die-forging*, *i.e.*, the accurate reproduction of metallic parts shaped by forms or cavities in enclosing dies, which dies are actuated by power hammers; 2. *Hammer-forging*, *i.e.*, the refining of billets, and the forming of billets and bars into shapes between flat dies and swages in power-driven hammers. The principal difference in the hammers employed is in construction. Die-forming or drop-hammers are rigidly constructed with respect to the alingment of the reciprocating hammer ram and the anvil, so that accurate die alignment is maintained. Forging hammers are constructed with the anvil separate from the balance of the hammer and mounted on an independent foundation.

**DROP-FORGINGS** or die-formed forgings made under drop hammers must embody in their forms, as outlined by R. E. W. Harrison, Developments in Modern Drop-forging and Their Relation to Current Machine Shop Practice, *Trans.*, A.S.M.E., 1936: 1. Minimum machining allowance consistent with proper cleaning up of finished surfaces; forgings true to die and perfectly matched; 2. Consistent and easy machinability; 3. Controlled grain flow of metal and avoidance of defects, as cold shuts, laps or seams; 4. Accurate sizing and locating of all surfaces which otherwise would require machining; 5. Minimum wastage of material, *i.e.*, small stub and flash; 6. Minimum number of actual forging and straightening operations; 7. Speed, precision, reliability and safety for the operator, in so far as the forging mechanism is concerned.

As these requirements are reduced to practice for a given material the major considerations become: 1. Die material, die design, and die setting; 2. Type of hammer; *a*, gravity drop with fixed fall, and hence the same energy available to accomplish each stage of the operation; *b*, power accelerated hammer, controlled as to power of each blow by the hammer operator. It is obvious that dies designed to operate in the one type of hammer will not be of the best form for use in the second type.

**DIE BLOCKS.**—Die blocks are made from nickel-chrome-molybdenum grain-controlled alloy steels, of which the following are typical:

| Carbon | Manganese | Chromium | Nickel | Molybdenum |
|---|---|---|---|---|
| 0.50–0.70 | 0.50–0.90 | 0.60–1.30 | 1.00–2.00 | ......... |
| 0.50–0.70 | 0.60–0.90 | 0.75–1.00 | ......... | 0.15–0.25 |
| 0.50–0.70 | 0.50–0.90 | 0.50–1.00 | 1.00–2.00 | 0.15–0.35 |
| 0.50–0.70 | 0.50–0.80 | 0.75–1.00 | 1.50–2.50 | 0.60–0.90 |

Blocks are forged on six faces—upset to destroy all original directional fibers, an essential factor, since the forging forces are exerted in all directions in a die cavity. Die block steel is never permitted to become cold from the time the ingot is cast until final tempering treatment. Blocks are normalized, quenched and tempered.

The block is machined and ground on the working face in order to secure a well-prepared surface for Brinell hardness testing. Blocks are hardened to a uniformity of 0.10 ball diameter. Converting this into scleroscope, it means approximately 4 to 5 points of hardness.

**Table 1.—Characteristics of Impact and Pressure Forging**

| Mechanism | Impact Forging | | Pressure Forging | | |
|---|---|---|---|---|---|
| | Hammers | Hammers | Hydraulic Presses | Steam Hydraulic Presses | Mechanical Forging Machines |
| Power application | Mass falling by gravity | Mass accelerated in fall by power | Continuous velocity and power through relatively long stroke | Continuous velocity and high power through relatively short stroke | Crank |
| Nature of deformation | Surface of forging worked more rapidly than interior | | Upsetting, piercing and extrusion | Interior worked more than surface which is restrained by die friction | Upsetting, piercing, extrusion |
| Practical limitations | Height of fall | Weight of anvil | Strength and flow of subject metal | Size of ingot to be forged | Size of machine elements |
| Products | Die forgings *<br>Surgical instruments<br>Shears<br>Pliers<br>Tableware<br>Automobile parts<br>Machine parts, etc. | Die forgings *<br>Billets<br>Bars<br>Shapes<br>Car axles<br>Crank-shafts<br>Airplane propellers<br>Crane hooks<br>Anchor chains<br>Automobile parts, machine parts, railroad parts, marine parts, etc. | Shell carcasses<br>Pressure containers<br>Tubes<br>Bends<br>Oxygen bottles | Reduction of<br>Ingots<br>Billets<br>Bars<br>Shapes<br>Die blocks<br>Propeller shafts<br>Massive machine parts<br>Ordnance | Die forgings *<br>Cluster gears<br>Automotive gears<br>Bolts, nuts, rivets<br>Valve tappets<br>Automotive parts<br>Machine parts |

* *Die-forgings* has been used as a more descriptive name for the products commercially known as Drop-forgings. The latter designation comes from the initial die forgings made on drop- or gravity-hammers.

The modern die block is furnished in four hardness ranges as follows:

| Hardness letter | A | B | C | D |
|---|---|---|---|---|
| Brinell ball diameter | 2.95–3.05 | 3.10–3.20 | 3.25–3.35 | 3.40–3.55 |
| Scleroscope | 60–56 | 55–52 | 51–48 | 47–44 |

The hardness is decided according to the type of impression in the block. The modern machine shop of 1937 can machine a die block as hard as 2.90 ball diameter, or approximately 62–63 scleroscope.

**DIE DESIGN.**—Drop-forgings are formed, usually of hot bar steel, between two dies, one reciprocating, in the faces of which are machined "half" impressions of the parts. Thus a parting line provides for insertion of the stock and withdrawal of the forged shape. To prevent sticking of the shape in the impression, draft is used on vertical surfaces. Hammers with slow return stroke pick-up require larger draft than those with properly accelerated return stroke, the range running from 10 deg. draft to 1 1/2 deg. draft, with 7 deg. generally employed in the slower hammers, and 3 deg. common to the more rapid double-acting hammers. The amount of deformation of the stock and its nature dictates the number and form of die impressions for drawing, fullering, roughing and finishing. The finishing impression, and sometimes the roughing impression, are surrounded by a gutter into which the flash, or excess metal, flows. Great care is essential in the design of the die for all functions to secure proper grain flow and minimum flash, since the flash, which is the thinnest section, governs the rate of plastic flow within the metal. One of the important characteristics of hammered forgings is the ability of the impact energy to sharply fill raised surfaces such as bosses and flanges. Only in rare cases is venting necessary to accomplish this purpose. A typical lower die for a drop-hammer is shown in Fig. 2. The upper die matches and is similarly machined.

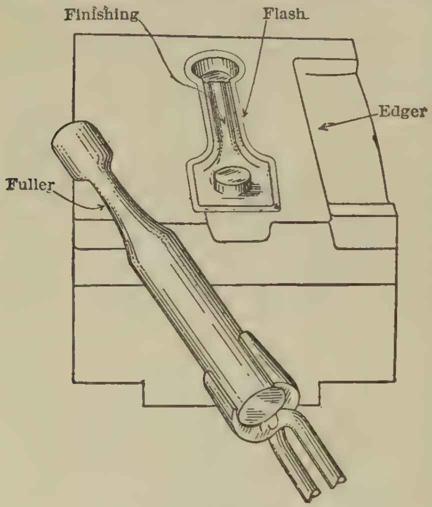


FIG. 2. Hammer Die

**DIE SETTING.**—The final blow struck on a die-forging, and producing the exact reproduction from the dies, also is that blow which has the least vertical displacement and hence absorbs the greatest amount of available energy in the least time. It, therefore, is essential in the reproduction of exact forgings that the dies be set so that the displacement load of the final impression is centered under the falling mass. Since die designing can only approximate this load distribution, it is necessary that adjustable yet rigid means of fastening the dies in the hammer be employed. Fig. 3 illustrates a typical dove-tail mounting for dies. Shims are used on the sides of the slot for left to right adjustment, and a series of dowels with graduated offsets provides adjustment from front to back.

**DROP FORGING PROCESSES.**—In the actual forging operation the hammer man manipulates the forging stock in the various impressions of the dies to secure the desired plastic flow in the finished forging. The heating of the metal is of prime importance to this manipulation, and requires: *a*, control of the rate of heating and avoidance of over-heating or of burning; *b*, forging with the stock at the proper temperature throughout; *c*, elimination of surface scale, usually blown off by blasts of air or steam between blows.

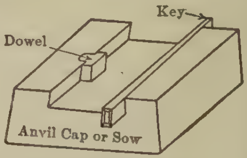

FIG. 3. Die Notch

The Subcommittee on Forging of the American Society for Metals in its Recommended Practice for Heating Steel Bars for Forging, Metals Handbook, 1936 edition, suggests practice for bars and billets up to and including 4 in. square or diameter The rate of heating suggested to bring the center of the stock to forging temperature for plain carbon steel of 0.50 carbon or less is five minutes per inch of diameter or thickness up to 3 in., with a slower rate for larger sizes. Slower rates are recommended for steels with higher carbon content. For alloy steels the rate recommended is six minutes per inch of diameter and thickness. In the "Metals Handbook" data are given on hot working stainless steels, "Fabricating and Finishing Stainless Steels," V. W. Whitmer.

Maximum forging temperatures, cited by Adam M. Steever, Factors Relating to the Production of Drop and Hammer Forgings, *Trans.* A.S.M., vol. xxv, 1937, are:

| | | | |
|---|---|---|---|
| 0.10 carbon steel | 2400° F. | 0.90 carbon steel | 2150° F. |
| 0.20 " " | 2375° F. | 1.00 " " | 2000° F. |
| 0.30 " " | 2350° F. | 1.50 " " | 1900° F. |
| 0.40 " " | 2325° F. | Monel Metal | 2100° F. |
| 0.50 " " | 2300° F. | Copper | 1800° F. |
| 0.60 " " | 2250° F. | Brass | 1400° F. |
| 0.70 " " | 2225° F. | | |

The cooling of the finished forgings requires attention in the higher carbon content steels, usually retardation of the cooling rate.

The larger drop-forgings are trimmed hot, the flash being removed by blanking in a trimming press after they are finished under the hammer. The forgings frequently are re-struck in the hammer for straightening and sizing. Hot trimming is essential when there is any hazard of introducing defects due to the tearing that occurs in cold trimming. Flash from aluminum forgings sometimes is removed by sawing.

The desirable features in a drop forge shop production line are specified in Fig. 4, which diagrams the principal processes involved. The chart is abstracted from a diagram by R. E. W. Harrison (Developments in Modern Drop Forging, and Their Relation to Current Machine Shop Practice, *Trans.* A.S.M.E., 1936). Greater detail is obtainable from Mr. Harrison's paper.

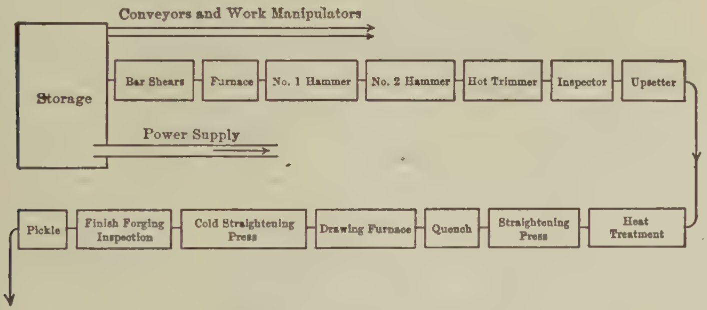

FIG. 4. Drop Forge Processes

**DROP-HAMMERS.**—Two types of hammers are available for drop forging. In the U. S., these are principally, *a*, board drop-hammers, and, *b*, steam drop-hammers. The hammers are rated by the weight of the reciprocating parts without dies. Principal dimensions are indicated in Tables 2 and 3, and Figs. 5 and 6, respectively, for the two types.

Since the hammer is the pacemaker for production, controls the accuracy of form, and represents the major equipment investment, the selection of the proper tool requires expert study. In general, shapes involving considerable drawing are not adapted for production on board drop-hammers. Relatively flat thin shapes best are produced in gravity drop-hammers and the smaller forgings usually are produced on this type. For specific recommendations the manufacturers of hammers should be consulted.

**HAMMER FOUNDATIONS.**—Typical drop-hammer foundations are shown in Figs. 5 and 6. It is essential that foundations be properly installed, that hardpan be the base of the foundation, or that piles be driven. Proper foundations insure the highest production, lowest maintenance costs, and freedom from shock transmission to surrounding structures.

**POWER REQUIRED FOR DEFORMATION.**—No generally accepted method of predetermining the power required to deform metals in forging hammers exists. Many tests on sample shapes under varying conditions have been made (R. H. Thurston, *Trans.* A.S.M.E., vol. v, p. 53, 1884, with copper cylinders; A. W. Moseley and J. L. Bacon, *Trans.* A.S.M.E., vol. xxvii, p. 605, 1906, with Bessemer steel plugs; W. T. Sears, *Am. Mach.*, March 10, 1910, with lead plugs), but the variables are so great and so little is

known of strains beyond elastic limits, that the practical application of formulas has not been developed.

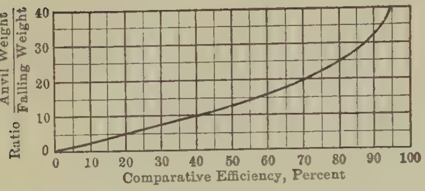

**Fig. 7.** Comparative Efficiency of Anvil Ratios

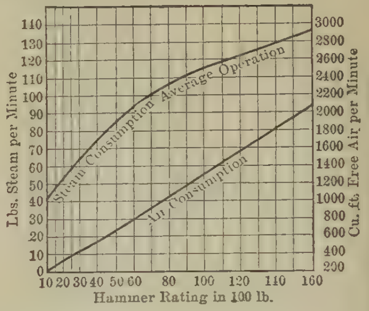

**Fig. 8.** Air and Steam Consumption of Power Drop Hammers

In the laboratories of the Chambersburg Engineering Company, Chambersburg, Pa., tests have been made in a specially constructed apparatus, which, with varying falling weights, velocities and anvils, simulates all conditions met in current practice. Not only are temperatures accurately controlled, but the rebound of the impacting die and the motion imparted to the entire structure are measurable. While useful data for designing hammers have been developed, all are empirical and incapable of reduction to formula. Three very useful points have been established, however, in the research conducted to the end of year 1936, *viz.*, 1. Within the range of present hammer velocities there is practically no difference in work accomplished by different falling weights and varying velocities to give the same available energy. Hence, within reason, it is desirable to forge on large rather than small hammers to save time and heat by shorter strokes; 2. The speeds of steam- or air-driven drop hammers as now constructed are near the economic limit; 3. The work done per blow is definitely related to the ratio of falling weight to anvil weight. Fig. 7 shows the relative efficiency of various ratios of anvil weight to falling weight. Ratio of falling weight to anvil weight of 20 : 1 or greater is standard practice for drop-hammers.

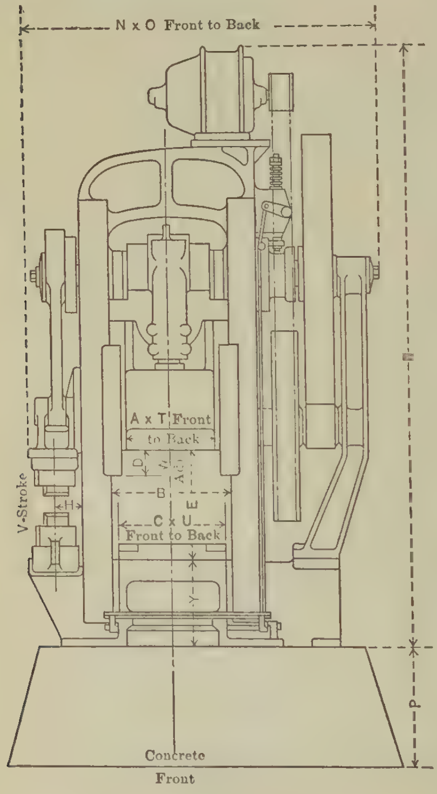

**Fig. 9.** Geared Trimming Press

**POWER CONSUMPTION OF DROP-HAMMERS.**—Gravity drop-hammers are driven by direct-connected motors, or are belt driven, and use energy only to lift the falling mass. Hence, the speed of the lift and friction within the mechanism readily indicate the power requirements. For individual drive it is common to calculate 1 Hp. per 100 lb. of rated falling weight. In group drive, the differential in operating cycles of the hammers will permit a reduction in peak load to as low as $3/4$ Hp. per 100 lb. of rated falling weight where six or more hammers of approximately one size are in the same group.

Steam- and air-driven hammer power consumption is shown in Fig. 8.

**TRIMMING PRESSES.**—Drop-hammer forgings require trimming to remove the flash. Crank-driven power presses are employed. For hot trimming, such presses are provided with a side shear for cutting the sprue, or stub end, from a bar. A typical trimming press is shown in Fig. 9. Dimensions are given in Table 4.

## 2. POWER-HAMMER FORGING

**TYPES OF POWER HAMMERS.**—By far the majority of hammer forged products in the United States are produced in double-acting hammers, actuated by steam or compressed air. These tools, rated by the weight of the falling parts, are made in two types, single frame forging hammers (Fig. 12), and double frame forging hammers (Fig. 13). Both types are manually controlled by the hammer man to deliver a range of blows, from a squeeze to the maximum velocity of the particular size. Common sizes range from 1000 lb. falling weight to 16,000 lb. falling weight; smaller sizes listed in Table 5 are used for tool dressing and general maintenance work; larger sizes than those listed in Table 6 usually are specially designed for a particular product. The most important individual characteristic of forging hammers is that the anvil is a separate structure from the frames and is mounted on a separately constructed foundation. (See Fig. 12.)

Recommended hammer sizes for the various sizes of forging stock are shown by Fig. 10.

**POWER CONSUMPTION** of double-acting hammers varies with every job, and when several hammers are served by a single power plant the stand-by requirements are materially reduced. Fig. 11 indicates the stand-by requirements of a single hammer for nor-

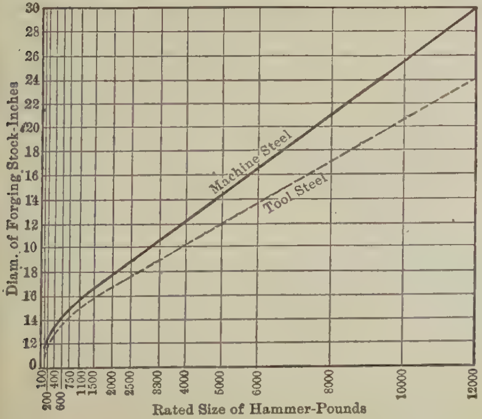

FIG. 10. Sizes of Forging Hammers for Various Sizes of Stock

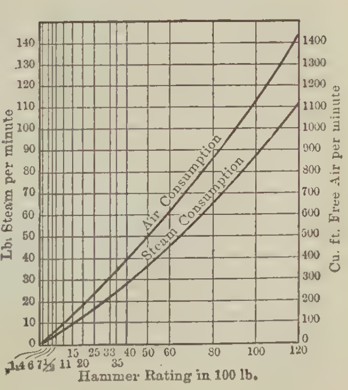

FIG. 11. Steam and Air Consumption of Forging Hammers

mal operation. For a group of six or more hammers, the stand-by requirements are frequently reduced 60%. No general data on power consumption are reliable, and the manufacturer should be consulted for specific information.

Fig. 12. Single-frame Forging Hammer

**WEIGHT OF THE ANVIL** as compared with the weight of the falling parts has a marked effect on the amount of forging accomplished per blow. Fig. 7 shows the relative efficiency of various ratios of anvil weight to falling weight. It has been found that a 15 : 1 anvil is the most economical for this type of hammer.

**HELVE- AND SPRING-HAMMERS.**—In addition to double-acting forge hammers, helve hammers, spring hammers, and self-contained pneumatic hammers also are employed for occasional specialized jobs. Helve hammers, as the name implies, carry the hammer head and upper die on a crank-driven helve. These hammers principally are used for drawing, tube shaping, etc.

*Between guides.

Self-contained pneumatic hammers have a crank-driven compressor piston, the chamber of which is connected to the hammer cylinder by proper valving. Limited in speed to that of the compressor crank, such hammers have characteristics which confine their use to certain specialized jobs.

**THE PRODUCTS OF THE HAMMER SHOP** cover a wide range of use, from machine tool bits to large crank-shafts and special shapes. In almost every case the subject material is steel, and in finishing, allowance must be made for the contraction occurring as cooling takes place from the forging temperature to atmospheric temperature.

**COMMERCIAL TOLERANCES** on size are given in Table 7 by E. J. Poole, Jr., Forging in a Tool and Alloy Steel Plant, *Heat Treating and Forging*, March, 1931. Forgings usually are made full to forging size and a tolerance allowed from the new size.

**FORGING METHODS.**—The selection and heating of forging stock, and its annealing and inspection, are beyond the scope of this publication. For such detail it is suggested that reference be made to Recommended Practice for Large Forgings, by John L. Cox, Metals Handbook, 1936 edition.

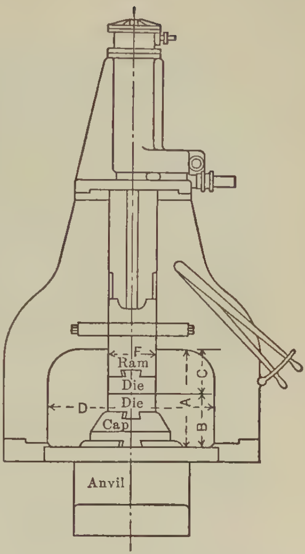

Fig. 13. Double-frame Forging Hammer

In forging operations, ingot reduction should be slight at the start and uniform on every face to properly consolidate the ingot structure. Too rapid operation will cause transverse fractures in the center, and may produce mechanical piping by working the surface metal faster than the center. It is important to cause the metal to flow in proper relation to the stress to be imposed on the subject. In shaping forgings to the desired form the preservation of proper grain flow is important.

**THE HAMMER FORGE SHOP** employs auxiliary equipment such as furnaces, work-holding and forming tools, crane and hoist material-handling means, and, for larger hammers, manipulators for the stock. A typical layout for the manufacture and maintenance of railroad forgings is shown in Fig. 14, a reproduction of the layout of the shops of the Norfolk and Western Railroad at Roanoke, Va.

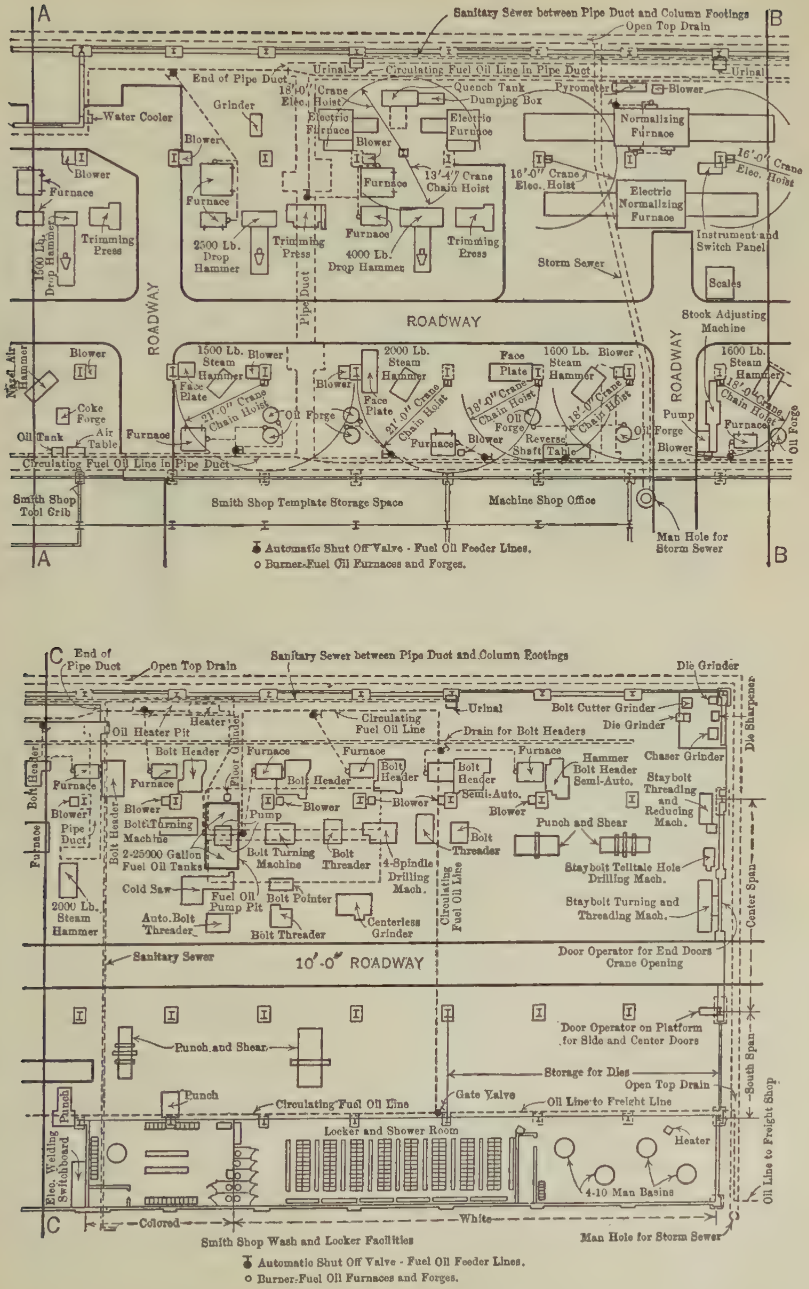

FIG. 14—*Continued.* Railroad Forge Shop Layout

## 3. HYDRAULIC FORGING *

Forging in hydraulic presses particularly lends itself to piercing, drawing, and extruding. The plastic deformations which occur in these operations are diagrammatically indicated in Fig. 15.

**PIERCING.**—In piercing, the shape of the punch has an influence on the flow. If the punch tip is pointed the layers are ruptured in a relatively shorter depth of piercing.

**Pressure of Fluidity,** that is, the point at which flow begins, increases as temperature decreases. Assume that at the temperature of the point of incipient fusion the pressure of fluidity at low velocities equals zero. From observation, and accepting that the pressure increases by a straight line law as the temperature falls, the pressure of fluidity may be calculated. For 0.45% carbon steel, observed pressure of fluidity at 1470° F. is $11\,^3/_4$ tons per sq. in., and at 2470° F., the region of incipient infusion, the pressure of fluidity is 0. Then $P_f$, the pressure of fluidity between these points, the velocity being slow is $P_f = 0.0118\ (2460 - T)$, where $T$ = temperature of the metal. Variations in carbon content in pearlite steel are insufficiently great to seriously affect this formula.

Pressure to produce flow, $P_m$, when the upward velocity of the pierced metal appreciably exceeds the downward velocity of the punch, can be determined within practical working limits by the formula $P_m = P_f\,[\{d^2/(D^2 - d^2)\} + 1]$, where $d$ and $D$ = diameter of piercing tool, and of the die, respectively. These conclusions will be modified if the velocity of the piercing tool deviates greatly from the normal speed of 3 in. per second common to shell piercing operations. Appreciably slower speeds will result in reduced flow, because of the cooling of the metal. Allowance will be required if the tools are not in normally good condition with regard to surface defects. If the piercing tool is tapered, greater pressure is required, because of frictional resistance on the tapered section. See chapter on Mechanical Treatment, in Bower, Hydraulic Forging, for formulas reflecting varying conditions.

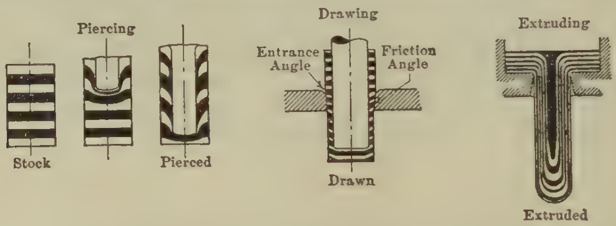

FIG. 15. Plastic Flow in Hydraulic Press Operations

**DRAWING** of shells or tubes generally is limited by the stress in the walls of the shell in tension. It is undesirable to stress steel walls more than 50% of their strength at 1650° F. A difference in temperature of 200° F. easily may exist on the two sides of the drawing die.

**EXTRUDING** † is limited in its usefulness in so far as hydraulic forging of steel is concerned. It is a major operation in the production of various cross-sectional shapes of lead, tin, zinc, copper, aluminum, etc. Such shapes in the form of rods or bars are made by forcing the metal through an aperture die by high pressure, producing smooth surfaces, free from flaws, to close dimensions, and generally imparting higher physical properties to the subject.

**PUNCHES AND DIES.**—Punches must be rigid to maintain concentricity, and tough to withstand abrasive action. Chrome-nickel steels generally have the longest life. Since scoring due to abrasion starts at the tip, renewable tough cast-iron tips frequently are used, in order to reduce the expense of renewals. Cooling and lubrication are required between piercing operations.

Dies for piercing operations commonly are constructed in the form of a steel jacket completely enclosing a renewable cast-iron liner, bored to suit the outside diameter required of the forging. Such dies have stripper plates to strip the forging from the punch, and the larger sizes are slidably mounted on the lower platen of the press to permit mechanical handling.

---

* The material here presented is principally an abstract of Hydraulic Forging, by Clifford O. Bower, printed by The Library Press, Ltd., London, England.

† Extrusion of Metals, by D. K. Crampton, *Trans.*, A.S.M., vol. xxv, 1937, contains much detailed information on extrusion of non-ferrous metals.

The mean average life of punches and die liners for forgings over 6 in. diameter is approximately 600 forgings. Smaller forgings may result in tool life of double or triple this amount.

Drawing dies are made of the hardest close-grained iron. It is common practice to use 20 deg. as an entrance angle, and 12 deg. as the friction angle of the die. See Fig. 15. Some dies have a curved entrance. Dies may be mounted in series for multiple drawing operations. The larger drawn forgings are produced on horizontal presses called *draw benches.*

**HYDRAULIC FORGING PRESSES.**—The piercing and drawing of steel forgings requires high pressures, which are most satisfactorily applied by means of hydraulically operated presses. The simplest forms are driven from constant-pressure systems, pressures of 1500 lb. or 2000 lb. per sq. in. being most general. The return stroke of the press ram usually is accomplished by return rams. Double-acting cylinders are uncommon, because of the inconvenience of packing. The simplicity of such presses permits construction adaptable to all conditions, and standards of working space, stroke, etc., are not established. Fig. 16 shows a typical shell drawing press.

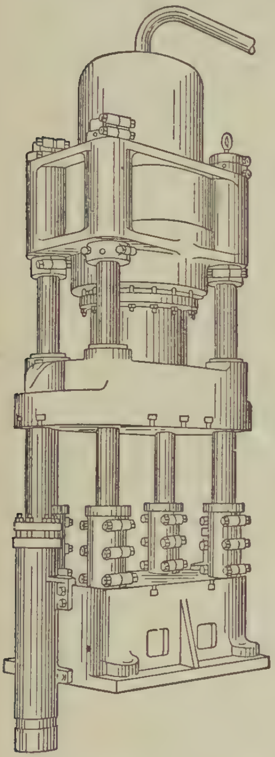

Fig. 16. Shell Drawing Press

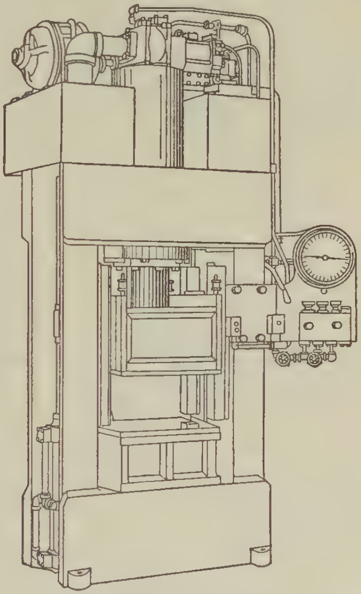

Fig. 17. Self-contained Drawing Press

Multi-pressure systems, using low pressure for non-working traverse motions, embody more complicated piping and valves. Such systems sometimes are more economical, but the economies should be proven before these systems are adopted.

For light operations and for non-ferrous metals, variable pressure systems are applicable. Self-contained presses, utilizing motor-driven rotary pumps and greater volumes of lower pressure fluid, are employed on light drawing and piercing work. Fig. 17 illustrates this type of press.

## 4. STEAM HYDRAULIC PRESSES

The reduction of ingots, the manufacture of large forgings and the refining of large sections, such as hammer die blocks, all require deep penetration into the mass of the forging. The steam hydraulic press is used for such work.

As the name implies, the presses are steam powered. The *press head* is lowered to the work by gravity, water being forced into the cylinder by air pressure in the storage tank. Steam admitted to the intensifier raises the water pressure during forging operations to as high as 6000 lb. per sq. in. Steam also is used to return the ram to its upper position.

The working spaces available in standardized steam hydraulic presses of the four-

column type together with dimensions are given in Table 8 and Fig. 19. Similar information for open-frame presses is given in Table 9 and Fig. 20.

**TOOLS.**—The mass of the forgings worked in steam hydraulic presses generally requires material handling equipment to manipulate the stock. This handling usually is done either by overhead cranes with power-driven chains for rotating the work, or by *manipulators* which grasp the forging and position it between the dies of the press. Mechanical means for handling cutting off tools and the like also is desirable with the very large presses.

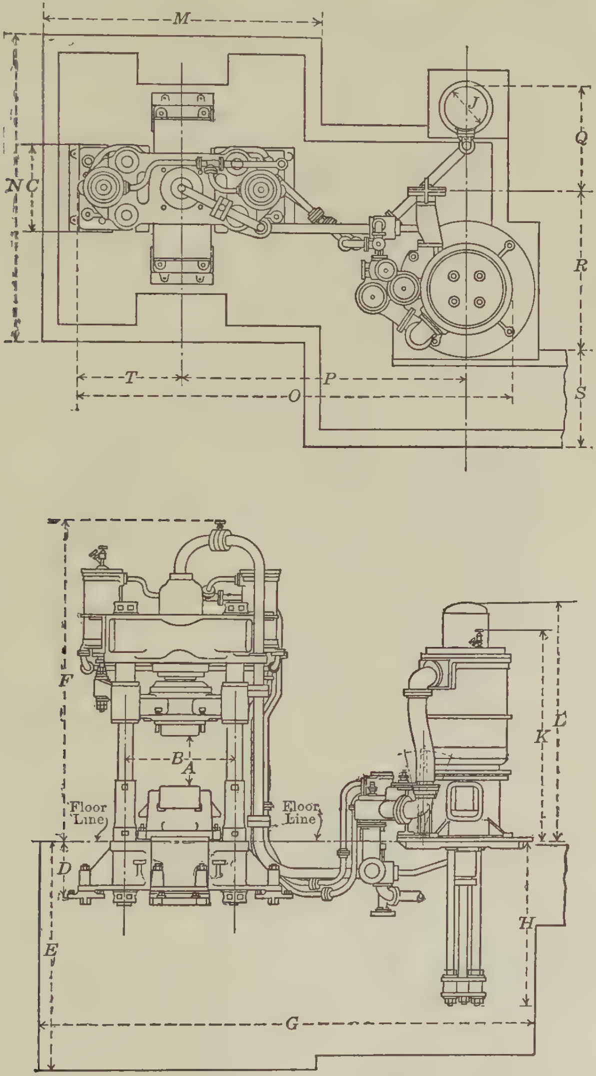

Fig. 19. Four-column Steam-hydraulic Press

**METHODS.**—Refer to Forging Methods, Hammer Forging, p. 19–04. The same methods are applicable to press forging.

**POWER CONSUMPTION.**—Neither the water nor the air employed in the steam hydraulic press are lost in operation. The steam is used only as forging pressure is applied

or released, and consequently is in direct proportion to the work done. The nature of the work, pressure required, temperature and characteristics of the subject material are so variable that a general statement of steam consumption is impractical.

## 5. MACHINE FORGING

The displacement of metal in closed dies, one of which is reciprocated by a crank mechanism, is plastic flow induced principally by upsetting and by piercing, or by both, for the mass production of identical shapes. Since each operation fills the die cavity under high hydraulic-like pressure, the stationary, or *grip*, dies are split to permit placing and extraction of the stock. The grip dies hold the stock, by frictional grip, against the forging force of the heading tool. Bar stock normally is used, and successive deformations to complete the shape are done in multi-impression dies. Positioning stops for each impression, and a *cut-off* to shear the finished forging from the bar are provided.

The plastic flow engendered in machine forging is illustrated by Fig. 21, wherein both upsetting and piercing have contributed to the desirable internal structure. In properly-designed dies, the stock is plastically flowing under compression in all impressions, resulting in a radial grain flow and refinement that is essential to a great variety of forgings, such as gear blanks, bearing races, etc.

**DIES.**—In a paper, Laws Governing Forging Machine Die Design, before the Am. Drop Forge Assoc., E. R. Frost gives three rules as follows: Let $d$ = diam. of bar.

**1.**—The limit of length of unsupported stock that can be gathered or upset in one blow without injurious buckling is not more than $3d$.

**2.**—Lengths of stock more than $3d$ can be successfully upset in one blow, provided the diameter of the upset made is not more than $1\,{}^1/_2\,d$.

**3.** In an upset requiring more than three diameters of stock in length, and in which the diameter of the upset is $1\,{}^1/_2\,d$, the amount of unsupported stock beyond the face of the die must not exceed $1d$.

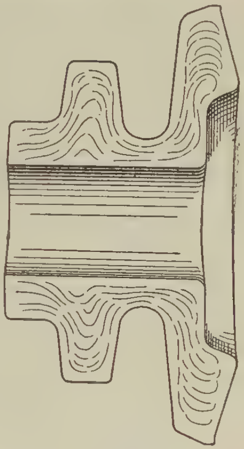

Fig. 21. Grain Flow in Machine Forging

The dies in a forging machine must resist pressure, abrasion and heat. In automatically-fed machines, the drawing of the temper of the dies generally reduces the forgings per dressing well below the number of forgings secured per dressing when hand fed. Cold-heading operations, as used in forming rivet heads, enjoy the longest die life. High chrome-nickel or vanadium steels, or other alloys, which retain their characteristics at relatively high temperatures are desirable when large radiation surfaces occur in the forming operation. Before being put in service, dies should be checked for hardness, which should conform to the requirements of the particular operation while avoiding excess hardness that may introduce brittleness. Fig. 22 indicating practical selection of die steels is reproduced from The Selection of Steels for Forging Machine Dies, E. R. Frost. Metals Handbook, 1936 edition, should be consulted for details regarding the selection and heat treatment of dies for machine forging, cold heading, etc.

*B* Chrome Steel
*C* High Tungsten Steel
*D* Low Tungsten Steel

**FORGING MACHINES.**—Requirements of the modern forging machine are: Grip sufficiently tight to prevent die separation and consequent fins; maintenance of alignment in both the gripping and upsetting mechanism to insure concentricity and to avoid breakage of punches; rapid starting and stopping; ease of control by the operator. Of major importance is the rigidity of the frame enclosing the mechanism. This must be extremely massive, and currently (1937) is made of a single steel casting, heat treated, and prestressed with heavy steel bars, shrunk in place. Commercial forging machines are nominally rated in inches of stock, which rating usually requires interpretation by the builder.

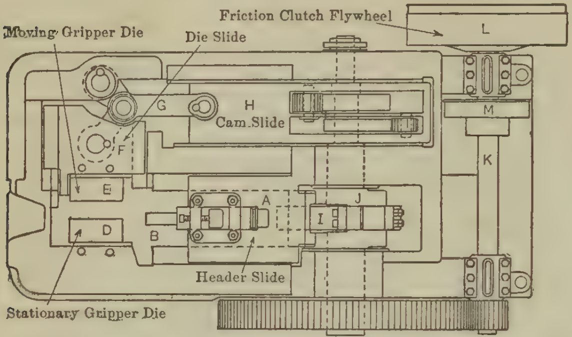

Fig. 23. Diagrammatic Arrangement of Horizontal Upset Forging Machine

Fig. 23 is a diagrammatic arrangement of a horizontal upset forging machine. The header-slide *A* carries the tool *B*. The bar from which the forging is to be made is gripped between the holding dies *D* and *E*, *E* being moved horizontally by the slide *F* at right angles to the movement of slide *A*. Movement of *F* is effected by the toggle *G*, which is actuated from the cam slide *H*, by complementary cams on the main crank-shaft. The header-slide is driven by the pitman *I* from the crank-shaft *J*. The driving shaft *K* is driven by a motor through the clutch flywheel *L*. In this forging machine, the clutch is a pneumatically operated friction clutch. Air is admitted to the clutch by a foot-controlled valve at the operator's end of the machine. When the crank-shaft has completed one revolution, a cam opens the valve and actuates a band brake *M* to bring the machine to rest. The die blocks *D* and *E*, actually may carry two or more impressions, and the header-slide two or more working tools, one above the other, each of which performs one of the successive forging operations necessary to complete the work.

Table 10 gives the specifications of typical heavy-duty horizontal forging machines.

**Table 10.—Specifications of High Duty Forging Machines**

**MECHANICAL FORGING PRESSES.**—For accurate sizing, coining, and the production of relatively simple symmetrical forgings, the mechanical forging press is a valuable contribution to processes, in that it reduces subsequent machining operations. The excessive rigidity and freedom from stretch built into the frame is of primary importance. The stationary die employed is not parted, as in the forging machine, but is solid. In other respects the die requirements are similar to those of the forging machine.

**GENERAL.**—The application of crank-driven forging machines to production of bolts, nuts, rivets, as well as to the manufacture of mechanical parts, has encouraged the development of many special machines for which specific information cannot be given. The manufacturers of such machines should be consulted.

## 1. GRAY IRON CASTINGS

**DEFINITION.**—Gray cast iron covers a wide range of alloys. Cast iron is a combination of iron with carbon, and other elements as silicon, manganese, phosphorus and sulphur. Nickel, chromium, molybdenum and other elements are used to obtain certain effects in the cast product. The fundamental governing material is graphitic carbon, associated with pearlite, ferrite, or both. Most commercial gray irons contain 2.50 to 3.75% total carbon (T.C.).

**USES.**—Cast iron is extremely important in the manufacture of machinery. Where bulk and inertia are important, its uses are well known. Machine tool frames and bases are made of cast iron in intricate forms, with high accuracy to finished dimension without undue machining. Machining time is a minor consideration in ordinary gray iron, as the material cuts rapidly, and, when properly made, has a smooth accurate surface which shows regularity and fine grain under the microscope. Its low cost recommends it for general purposes, limited by its physical properties and by the detailed method of manufacture.

**PHYSICAL PROPERTIES.**—In gray cast iron, carbon is held in solution in the molten state, but is precipitated in flat flakes like mica when the metal freezes in the mold. These flakes form weakening planes which tend to lower strength when subjected to stress. To the casting buyer, this condition is important only when a part is subjected to stress.

**Strength Properties.**—Tensile strength of gray cast iron ranges from 20,000 to 60,000 lb. per sq.in.; 25,000 to 35,000 lb. is a fair average, unless special, high-strength cast iron is specified. Transverse strength may be made to range from 1500 to 6900 lb.on a 1.2 in. diam. bar, 18 in. between supports. Hardness varies inversely with machinability, although in direct proportion; it may be varied from 100 to 400 Brinell by increasing or decreasing different alloy elements or by hastening or retarding cooling of the iron in the mold. The ultimate compressive strength of iron ranges from 70,000 lb. to 200,000 lb. per sq. in.

**Wear Resistance.**—The early explanation that particles of free graphite form a lubricating element which prevents binding or galling when gray iron is used with similar material, or with steel, is not now generally accepted. J. W. Bolton offers a theory that the heterogeneous structure provides an interspersing of soft and hard materials, like bearing metals and bronzes. Wear resistance of gray cast iron under certain conditions is extraordinary. Examples are: automobile cylinders, subjected to sliding friction of cast-iron piston rings; slides on machine tools. For more severe wear, so-called chilled iron, resulting from rapidly cooling the surface of gray iron castings, finds wide use. Cast-iron car wheels are examples. Chilled cast iron also is used for die blocks, gears for certain services, scrapers, conveyor buckets, etc. White cast iron, low in Si, having a white fracture throughout, also resists wear extremely well, and is used for balls and liners for grinding machinery.

**Corrosion Resistance.**—Gray iron does not deteriorate rapidly under normal corrosion conditions. Special alloy cast irons are resistant to commercial acids, mine waters, and the extraordinary hazards of machinery in the chemical, tanning, fruit preserving and allied industries. See p. 3–24. Strong dense irons, low in total carbon and silicon are acid resistant. High-silicon irons, about 14% Si, resist all acids except hydrofluoric and hot concentrated hydrochloric acids. These irons are brittle and practically unmachinable, but are useful in chemical industry, notably the production of nitric acid. Gray iron has many applications in production of caustic or alkaline products, where high-nickel, austenitic types are preferred, particularly for boiling kettles.

[1] Mo = 0.07. [2] Mo = 0.45. [3] Not suitable for heavy section. [4] Cu = 4.07; a martensitic iron not at present (1937) commercially used. [5] Not suitable for light section. [6] Cu = 6.12; an austenitic iron for high temperature and corrosion resistance. [7] Bars cast to 1.4 in. and machined to 1.20 in. diameter. [8] Modulus of Rupture = (Transverse breaking load of 1.20 × 18 in. bar) × 26.5.

**Impact Resistance.**—The engineering conception of gray cast iron generally is a brittle material, incapable of shock or impact resistance. However, gray iron castings are used in many places where knowledge of impact resistance is important. Examples: Pistons for internal combustion motors, and car wheels, which are specified and purchased on impact tests.

A far-reaching investigation undertaken by A.S.T.M. Committee A–3 on the relation of impact properties to chemical and physical properties of cast-iron was completed and reported in 1933. See *Proc.* A.S.T.M., 1933. The developed data of the investigation are given in Table 1. Each test includes an investigation of 3 to 6 sets of specimens with varying chemical analyses and different types of foundry conditions. Beside impact values, transverse, tensile and compression tests were made and hardness values established.

In Table 1, summarized from data presented, average values are given. Brinell hardness is an average of values taken at the rim, center and midway on the cross-section of test specimens. The final columns include impact values established on unnotched specimens by the Charpy and Russell pendulum type testing apparatus, the specimen being supported rigidly near the ends and struck at the center. Three of the columns are variations of the falling hammer test on a specimen 1.20 in. diam. supported at 6 in., 5 in., and 6 in., respectively. The first of these falling hammer tests used a 25-lb. weight from an elevation of 2 in., with increasing increments of $1/2$ in. The table gives average height from which hammer dropped when the bar broke. The second of the falling hammer tests was on specimens supported at 5 in. centers with an 11-lb. weight starting at 1 in., with increasing increments of 1 in. The third summarizes average tests at 6-in. centers with 25-lb. weights starting at 1 in. with increasing increments of 1 in.

The impact test, essentially a measure of energy absorbed in breaking bars, may be expressed by the work done, namely force times distance through which force moves. Results of Charpy and Russell tests are in foot-pounds. The others may be computed from the drop and weight of hammer.

**Electrical Properties.**—Castings may have a wide range of electrical properties, depending on alloying elements. Non-magnetic cast iron is obtainable, an important factor in signal equipment or electrical control machinery. Non-magnetic iron contains a relatively large amount of Ni and Mn. The electrical resistivity of pure iron according to Dr. T. D. Yensen is 9.87 micro-ohms per cu.cm. at 20° C. Interruptions in resistivity are provided by other elements, especially carbon. The resistivity of soft gray iron is 74.62 micro-ohms, and of hard iron 98.04 micro-ohms per cu.cm. (J. E. Hurst, Metallurgy of Cast Iron, p. 270.)

According to Hatfield (Cast Iron in the Light of Recent Research) magnetic properties of cast iron may vary between wide limits ranging from low permeability and high coercive force, for permanent magnets, to high permeability, low coercive force and low hysteresis loss for electrical machinery.

**Thermal Properties.**—Specific heat of gray iron has not been determined accurately for all temperatures, but the International Critical Tables give it as 0.13 between 0 and 100° C. Hurst supplies accumulated data to show that it varies in pure iron from 0.1111 at 100° C. to 0.1948 at 1600° C. The addition of various elements appears to raise the specific heat.

Thermal conductivity according to Donaldson, *Proc.* I. M. E., 1928, varies from 0.110 to 0.137 calories per cm. per sec., and decreases with temperature increase. Values obtained depend on composition and structure of gray iron. Si lowers conductivity as does Ni, Mn and V. Chromium and tungsten tend to raise conductivity.

**Growth.**—Gray cast iron expands when heated, and unless certain limits are exceeded, returns to its original size when cooled. Growth is the permanent increase in volume that occurs in some grades of gray iron under repeated heating and cooling. The critical point which influences growth is about 1200° F., but in the presence of steam or corrosive elements, the change occurs at lower temperature. Different irons show varying susceptibility to this change, which is accompanied by loss in strength. Rugan and Carpenter (report to British Iron & Steel Inst.) showed that growth is proportionate to Si content in the range from 1.0 to 3.5% Si; that P, S, and Mn all are elements that retard this action. Piwowarsky (*Trans.* Am. Fdymen's Assoc., 1926) shows that superheating molten iron tends to reduce growth in resulting castings. This is ascribed by Bolton to extremely fine graphite formation. Hurst (*Fdry. Trade Jour.*, Aug. 12, 1926) states that growth tendency is inversely proportional to maximum strength, and directly proportional to modulus of elasticity.

**Fatigue Resistance.**—Fatigue tests conducted at the Universities of Illinois and Wisconsin (J. B. Kommers, *Proc.* A.S.T.M., vol. xxix, Pt. 2, p. 100, 1929) included tension, compression, transverse, Russell impact, and rotating beam fatigue. These show ratio of endurance limit to modulus of rupture to average 0.26. See also p. 7–12.

**EFFECTS OF ALLOYING ELEMENTS.**—In making calculations of the common elements in gray cast iron, the Am. Fdymen's Assoc. suggests:

**Silicon** softens iron, opens the grain, lowers density; in excess, it weakens and hardens iron and causes sponginess in heavy sections.

Table 2.—Minimum Breaking Loads for Transverse Tests of Cast-iron Test Bars

| Test Bar | | Class No. | | | | | | |
|---|---|---|---|---|---|---|---|---|
| Diam., in. | Distance between supports, in. | 20 | 25 | 30 | 35 | 40 | 50 | 60 |
| | | Minimum Breaking Load at Center, lb. | | | | | | |
| 0.875 | 12 | 900 | 1025 | 1150 | 1275 | 1400 | 1,675 | 1925 |
| 1.2 | 18 | 1800 | 2000 | 2200 | 2400 | 2600 | 3,000 | 3400 |
| 2.0 | 24 | 6000 | 6800 | 7600 | 8300 | 9100 | 10,300 | ....... |

**Sulphur** hardens iron, closes the grain, increases density; in excess, it causes defects and may weaken the metal. It increases tendency to chill white in thin sections.

**Phosphorus** increases fluidity of iron; in excess, it lowers impact value. It fosters formation of porosity in heavy sections.

**Manganese** increases density of iron; it has strengthening effect up to around 1.00 Mn; in very small amounts it has a softening effect. Over 1.00, Mn has a tendency to harden iron.

**Combined Carbon** (CC) increases hardness and toughness of iron; it increases strength below 0.80 C, decreases strength when in excess, and closes the grain.

**Graphitic Carbon** (GC) increases softness and machinability in iron, weakens it, opens the grain, and decreases density.

## 2. SPECIFICATIONS FOR GRAY IRON CASTINGS

**CLASSIFICATION.**—A.S.T.M. tentative specification A48–36 covers general gray iron castings not covered by other existing A.S.T.M. specifications, and applies to castings where strength is a consideration. Its purpose is to list and classify cast irons and gray iron castings according to minimum strengths of tensile test bars as follows:

| Class No. | 20 | 25 | 30 | 35 | 40 | 50 | 60 |
|---|---|---|---|---|---|---|---|
| Min. Tensile Str., lb. per sq. in. ........ | 20,000 | 25,000 | 30,000 | 35,000 | 40,000 | 50,000 | 60,000 |

Transverse tests are optional and minimum breaking loads are given in Table 2. By agreement between manufacturer and purchaser deflection values in transverse test may be specified. Transverse tests are made on bars as cast, with central loading between supports. To correct test result to standard diameter, breaking load obtained in testing the bar is divided by correction factor, given in Table 3.

Controlling dimension is diameter of bar at fracture. Rate of application of load should

Table 3.—Correction Factors for Transverse Cast-iron Test Bars

| 0.875 in. Diameter Bar | | | 1.20 in. Diameter Bar | | | 2.00 in. Diameter Bar | | |
|---|---|---|---|---|---|---|---|---|
| Diameter of Test Bars, in. | Correction Factor | | Diameter of Test Bars, in. | Correction Factor | | Diameter of Test Bars, in. | Correction Factor | |

| .925 | 1.181 | .946 | 1.30 | 1.271 | .923 | 2.10 | 1.158 | .952 |

**Table 4.—Dimensions of Test Bar and Controlling Section of Casting for Transverse Tests**

| Controlling Section of Casting | Test Bar | Dimensions of Test Bar, in. | | Distance between Supports in Transverse Test |
|---|---|---|---|---|
| | | Diameter | Length | |
| 0.50 in. max. | A | 0.875 | 15 | 12 in. |
| 0.51 to 1.00 in. | B | 1.20 | 21 | 18 in. |
| 1.01 to 2.00 in.* | C | 2.00 | 27 | 24 in. |

* For sections over 2.00 in., test bar C or a larger bar may be used by mutual agreement.

produce fracture in not less than 15 seconds for the 0.875-in. bar; 20 sec. for the 1.2-in. bar; 40 sec. for the 2.0-in. bar.

Tension and transverse test bars are cast separately from the casting; 3 tension, 3 optional tension, and 3 transverse test bars are required. Size of test bars depends on controlling section of the casting, and the corresponding transverse test bar is used, as shown in Table 4. Form of tension test bars is shown in Fig. 1, and dimensions in Table 5. Instead of using the separately cast tension test bar, it is optional to use test specimens machined from the transverse test bars. Form and dimensions of the optional tensile test bars then shall give a minimum section in the breaking area as follows:

| | Test Bar A | Test Bar B | Test Bar C |
|---|---|---|---|
| Diameter | 0.505 in. | 0.800 in. | 1.25 in. |
| Length of reduced area | Shall be equal to or greater than diameter | | |

For sections of castings over 2 in., test bar C or a larger test bar may be used by agreement between manufacturer and purchaser.

The previous correlation is only approximate and may need modification for complicated castings. Tension test specimens must so fit holders of testing machine that the load is axial; self-aligning shackles are recommended.

There is no definite factor for correlation between tensile and transverse strengths for various types of gray cast iron. Table 3 shows minimum values only. If manufacturer and purchaser agree on transverse tests to govern, the proper range of transverse values may be taken from the table or determined by pouring transverse and tension bars to establish a correlation for that particular cast iron. Test bars should be made under the same sand conditions as the casting, poured from the same ladles of iron as the castings, and as nearly as possible at the same temperature. They should receive the same mechanical and thermal treatment as the castings, and in heat treatment, should be treated adjacent to the castings they represent.

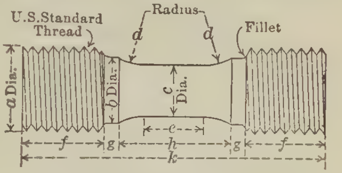

Fig. 1. Standard Test Specimen

**GRAY IRON CASTING COMPOSITION.**—The compositions of castings given in Table 6 are not absolute, but are a guide for general practice. Designers and purchasers of castings should rely on specifications of desired physical properties and should not attempt to designate chemical analyses. Questions of technique and skill permit competent foundrymen to produce a satisfactory product which may vary from these empirical compositions, and individual practice may offer a superior product which does not accord with the compositions recommended in Table 6.

**Shrinkage of Castings**—The allowance necessary for shrinkage varies for different kinds of metal, and the different conditions under which they are cast. For castings

[1] Ladle additions of Ni, 1.25, Cr, 0.30, are used.

[2] For auto cylinders general practice is to run a Brinell hardness test in the bore; a desired hardness is 180 Brinell. Emphasis is further directed to obtaining a machinable iron (no hard corners or spots). This analysis with Ni, 0.60, Cr, 0.25, Brinell 190, is a low-nickel mixture.

[3] An addition of 1.25% nickel is added to the ladle. Brinell 190.

[4] Ladle addition of Ni, 1.00%.

[5] Light 3- to 5-in. diam., higher Si and C; heavy, 10 to 12 in. diam., lower Si and C.

where the thickness runs about 1 in., cast under ordinary conditions, the following allowance can be made:

| | | | |
|---|---|---|---|
| For cast iron, | 1/8 inch per foot. | For zinc, | 5/16 inch per foot. |
| " brass, | 3/16 " " " | " tin, | 1/12 " " " |
| " steel, | 1/4 " " " | " aluminum, | 3/16 " " " |
| " malleable iron, | 1/8 " " " | " britannia, | 1/32 " " " |

Thicker castings, under the same conditions, will shrink less, and thinner ones more, than this standard. The quality of the material and the manner of molding and of cooling the casting also will make a difference. W. J. Keep (*Trans.* A. S. M. E., xvi, p. 561, 1895) gives the following "approximate key for regulating foundry mixtures" so as to produce a shrinkage of 1/8 inch per foot in castings of different cross-sectional area:

| Size of casting, in. sq. | 1/2 | 1 | 2 | 3 | 4 |
|---|---|---|---|---|---|
| Silicon required, percent | 3.25 | 2.75 | 2.25 | 1.75 | 1.25 |
| Shrinkage of a 1/2-in. test-bar, in. per ft. | 0.125 | 0.135 | 0.145 | 0.155 | 0.165 |

**Table 7.—To Determine Weight of Casting from Weight of Pattern**

(Allowance must be made for the metal in the pattern)

| A Pattern Weighing 1 lb. When Made of | Will Weigh When Cast in | | | | | |
|---|---|---|---|---|---|---|
| | Cast Iron | Yellow Brass | Gun Metal | Zinc | Copper | Aluminum |
| Baywood | 8.8 lb. | 9.9 lb. | 10.3 lb. | 8.5 lb. | 10.5 lb. | 3.2 lb. |
| Beech | 8.5 | 9.5 | 10. | 8.2 | 10.1 | 3.1 |

## 3. FOUNDRY MELTING PRACTICE

### Cupola Practice

The American cupola furnace is a vertical, cylindrical stack of riveted mild-steel plate, elevated on columns above the floor level, with semi-circular drop doors at the bottom. The stack has small openings at front and back, close to the bottom, and a suitable opening above at a predetermined level for charging metal and fuel. It is surrounded by an enclosed, steel-plate wind belt, continuous about the lower portion of the stack, connected with a blower and communicating with the interior of the cupola through a series of openings or tuyeres. An inner lining of refractory brick or blocks is built from top to bottom inside the stack. The lining is 4 1/2 to 10 1/2 in. thick, depending on overall diameter of the cupola.

In operation the bottom doors are closed and a molding sand bottom 3 to 10 in. deep, is sloped properly to direct molten iron to the tap hole. Special refractory shapes close the breast or front opening, and a special shape inserted at the back of the cupola at a higher elevation drains slag. Air is delivered at pressures of 10 to 25 oz. per sq. in. by blower or fan to the wind belt and enters the cupola through the tuyeres.

Special types of cupolas admit blast in a variety of ways. The simpler forms, as in the standard cupola of Whiting Corp., Harvey, Ill., have one or two rows of tuyeres. The bottom row is rectangular, expanding inward to the inside of the cupola, the discharge area being approximately double the inlet area. The upper row, of similar construction, supplies air to consume gases generated by the coke at the lower level. Appropriate dampers or blast pipe gates govern the amount of entering air, or blowers can be regulated to give correct pressure and velocity of air. Table 8 shows a simple calculation of tuyere areas based on inner lining of the cupola.

At a melting ratio of 8 lb. iron to 1 lb. coke, 30,000 cu. ft. of air usually is assumed to be required for melting 1 ton of iron. This ratio is not arbitrary, and a 10 : 1 melting ratio is common. Table 9 summarizes the actual performance of a number of cupolas, based on studies by Dr. E. E. Marbaker.

### Table 8.—Calculation of Tuyere Ratios

| Effective Diam. Inside Lining, in. | Area Inside Lining, sq. in. | No. of Tuyeres | | Dimensions of Primary Tuyeres, in. | | Total Area of Primary Tuyeres, sq. in. | | Total Tuyere Area, sq. in. | | Ratio of Total Tuyere Area to Area Inside Lining | |

| Total heat evolved (14,550 B.t.u. per lb. carbon), B.t.u. | 19,788,000 | 59,510,000 | 43,650,000 | 36,957,000 | 61,255,500 |
| Melting efficiency, percent, $= \left\{ \frac{\text{(B.t.u. required} \times 100)}{\text{B.t.u. evolved}} \right\}$ | 60.8 | 39.2 | 34.4 | 53.5 | 31.4 |
| Theoretical air necessary, cu. ft. (Carbon consumed × 143 cu. ft. per lb.) | 194,480 | 585,000 | 429,000 | 363,320 | 602,030 |
| Total air supplied, cu. ft. (Cu. ft. per min. × 60) | 192,000 | 585,000 | 480,000 | 582,000 | 444,000 |
| Excess or deficiency of air, percent | − 1.00 | 0.00 | + 11.9 | * See note | − 26.2 |

* Calculation of B.t.u. necessary to melt and superheat iron to pouring temperature: Let $Q$ = heat required to melt and superheat 1 lb. of iron; $T_m$ = melting temperature = 2260° F, average; $T_n$ = average temperature of blast air = 60° F; $T_p$ = temperature of iron at spout, deg. F; $H$ = specific heat of iron up to 2260° F = 0.19; $h$ = specific heat of iron up to 2800° F = 0.23; $L$ = latent heat of fusion of iron = 41.5 (say 42) B.t.u. per lb. Then

$$Q = H(T_m - T_n) + h(T_p - T_m) + L = \text{B.t.u. required} = \text{pounds melted} \times Q.$$

For example, as in No. 5: Heat for melting = 0.19 (2260 − 60) = 0.19 × 2200 = 418
Heat for superheating 0.23 (2650 − 2260) = 0.23 × 390 = 90
Latent heat of fusion = 42
Total = $Q$ = 550

Total B.t.u. = 35,000 × 550 = 19,250,000.

Efficient cupola operation comprises more than obtaining hot iron with the lowest coke consumption. Smoothness of operation, uniformity, freedom from bridging and tap hole difficulties, and economy by avoiding frequent lining troubles are factors. The

A. F. A. Committee on Gray Iron Castings (*Trans.* A. F. A., vol xxxix, p. 49, 1931) has formulated recommendations for operating a 54-in. cupola, summarized below.

**RECOMMENDATIONS FOR OPERATION OF A 54-IN. CUPOLA. Lining.**—To line a new cupola or reline an old one, use good grade cupola block of proper dimensions, laid with close joints filled with fireclay mixture. Typical mixtures are: *a.* 1 part fireclay, 1 part molding sand, 1 part sharp core sand; *b.* 1 part blue clay, 1 part finely-ground firebrick, 2 parts fire sand or heavy molding sand; *c.* 1 part fireclay, 2 parts molding sand. The shape of lining depends on practice, and may be classified under two types: 1. Straight side, *i.e.*, straight from bottom doors to charging door. 2. Boshed, *i.e.*, a 3 to 6 in. projection at top of tuyeres, tapering to the straight side just above melting zone. After each heat, chip out badly burned brick, and patch with new brick, maintaining original outlines as closely as possible. A new breast brick or tap hole should be used if tap hole has become too large for desired flow of metal. Tap hole should be about 1 in. diam. at the shell for intermittent tapping and not over 2 or 3 in. long; for continuous operation size should be adjusted to melting rate. Its location is just at the level of the sand bottom. The slag hole should be located 2 to 4 in. below bottom of tuyeres. Its size depends on thickness of lining and size of cupola, and usually is 1 to 2 in., either round or square.

**Tuyeres.**—Area of tuyeres should be approximately $^1/_3$ area of cupola at the tuyeres. Height of tuyeres should be 10 to 20 in. above center of the sand bottom, depending on amount of iron required at one tap. They should be as nearly continuous as possible with a vertical opening 3 to 5 in. high. For ordinary conditions, use only one row of tuyeres.

**Bottom.**—Bottom doors should be securely propped and rigid, to eliminate possible cracking of sand bottom and running out of iron. Bottom sand should be riddled rich heap sand, at same temper as for molding, carefully rammed and sloped with a 1 to 2 in. pitch from all directions to the tap hole. All-new, or too wet sand should not be used. Make bottom 5 to 6 in. thick at tap hole.

**Lighting.**—Flat wood is laid to protect the bottom while charging heavier wood. The wood usually is ignited through the tuyeres, or by ignited oil-soaked rags dropped from the charging door; sufficient wood then is added to ignite the coke thoroughly. From 65 to 75% of the coke for the bed next is charged and allowed to burn until the whole bed is cherry red. The remaining coke is added and leveled to receive the charge of iron. The coke bed should be high enough to melt iron in 8 to 10 min. after blast is put on. This usually requires 2,000 to 2,400 lb., depending particularly on height of tuyeres above the bottom and shape of cupola well. The above amount should raise the bed 40 to 50 in. above the tuyeres. In starting a new cupola, it is safe to use a coke bed 45 in. above the upper edge of the tuyeres. The upper edge of the melting zone is easily located by examining the lining after the first heat. It is wise to determine height of bed coke with a measuring rod. At least one hour should elapse between lighting of the cupola and putting on of the blast. A period of 2 hr. is better to thoroughly warm the charge before melting begins.

**Charges and Charging.**—All materials should be weighed and loaded systematically according to size of pieces and composition. The proper system is best determined by experiment and practice. Good practice charges the heavy pieces around the lining of the cupola; this tends to better blast penetration. Under ordinary conditions, the charges should be 2,000 to 3,000 lb., of the same weight, and in the approximate ratio of 10 lb. of iron per lb. of coke. Charging may be either mechanical or by hand. It is not good practice to use in the same heat, mixtures of widely different composition. If this is necessary, the mixtures may be partly separated by an extra charge of coke.

**Flux** should be a good grade of limestone. For long heats and continuous melting, the limestone should be 2 to 4 % of weight of the iron charge, with 4 to 5 lb. of fluorspar, per charge.

**Blast.**—Volume of air required depends on rate of melting, coke ratio and quality of coke; 30,000 cu. ft. of air per ton of iron melted is generally assumed. Blast pressure varies with style and size of tuyeres, height of stack, size of coke and metal used in the charge. Pressure ranges from 6 oz. to 24 oz., depending on the above conditions. For uniform melting, volume should be constant and pressure varied. Every cupola should have volume and pressure gages and means to adjust the volume of air delivered to the wind box. For a given cupola and blower, melting rate increases as the square root of the pressure. Power required varies as cube of melting rate.

For a 54-in. cupola, one blower manufacturer recommends a blower of 22, 25, or 29 cu. ft. displacement. To obtain 6000 cu. ft. per min. in accordance with the recommendation, it will be necessary to operate the blowers at 272, 240, or 206 r.p.m., respectively. With 10% slippage allowance the speeds will be 299, 264, or 227 r.p.m. To use the blower as a volume meter, it is necessary only to know its displacement and its speed. In calculations, the 10% slip correction should be included. For example, with 25 cu. ft. blower displacement and 250 r.p.m., tachometer reading, the volume supplied, allowing 10% slip, will be $0.90 \times 250 \times 25 = 5625$ cu. ft. per min., which is less than desired; hence the blower should run at 264 r.p.m. While the blower can be used as a volume meter, slippage is difficult to determine accurately; a standard orifice is recommended for accurate measurement of air supply.

CUPOLA COMBUSTION.—Since the combustion of 1 lb. of carbon to $CO_2$ or CO evolves 14,600 and 4,450 B.t.u. respectively, cupola economy demands that operation shall produce a minimum amount of CO. A clearly defined melting zone is established in a completely charged cupola, which should be slightly above the tuyere area, as no melting occurs below this level. If air passes through the cupola in uniform quantity and velocity and encounters a cylindrical coke column, uniform in shape, size and area exposed, combustion occurs uniformly. This condition is ideal rather than practical. The U. S. Bureau of Mines, by analysis of gas samples obtained from the center to the outside edge at different levels, has located the melting zone as regards its upper level. In a cupola lined to 27 in. diam. at the tuyere level, with 1000 cu. ft. of air per min. at

**Table 10.—Capacity Table of Steel Pressure Blowers for Cupola Service***

| Cupola | | Tuyeres | | Iron | Air | | Blower | | | | | Pipe | |

| 78 | 4778 | 12 | 955 | 48,000 | 12,000 | 15.66 | 1318 | 14 | 12,520 | 109.00 | 21 | 32 | 2300 |
| 84 | 5542 | 12 | 1109 | 56,750 | 14,200 | 16.20 | 1410 | 16 | 13,380 | 132.75 | 21 | 33 | 2400 |
| 87 | 5945 | 16 | 1189 | 61,600 | 15,400 | 16.50 | 1340 | 16 | 15,675 | 155.66 | 22 3/4 | 35 | 2400 |

* Air pressure less than given in the table indicates too much air flowing, with more power required to drive the blower than is specified. Blast gate in pipe between blower and cupola should be closed sufficiently to reduce the Hp. to that given in table. Volume then will be correct for highest melting efficiency obtainable with cupola, regardless of proportions or resistance, table being based on the greatest resistance usually encountered.

5.3 oz. per sq. in. pressure, the percentage of free oxygen at any given point was taken to locate the area of complete combustion. The upper level of the melting zone thus was shown to be more or less conical, extending from a height of 7 in. at the lining to about 28 in. at the center.

**AIR SUPPLY TO CUPOLAS.**—Two common types of blowing units are used to supply blast pressure to cupolas. The positive pressure type delivers a fixed volume of air, regardless of the pressure against which it operates. Cupola blowers of this type are driven by motors coupled to the main shaft of the blower, or by multiple V-belt drives. Table 10 gives capacities of positive pressure blowers for cupola service.

The other common type of unit used is the centrifugal compressor. Certain centrifugal compressors have an auxiliary blast gate, with suitable motor-driven gear control and electrical operating devices, to permit delivery of a fixed weight of air into the cupola blast pipe. Based on using coke of 88% fixed carbon, and allowing 5% air leakage, the rate of air delivery for various melting ratios is

| Melting ratio............ | 12 to 1 | 11 to 1 | 10 to 1 | 9 to 1 | 8 to 1 | 7 to 1 |
|---|---|---|---|---|---|---|
| Lb. of air per min......... | 25.3 | 26.0 | 26.8 | 27.8 | 29.0 | 30.6 |

See Kent's Mechanical Engineers' Handbook—Power, pp. 1–55 to 1–88, forming Vol. 2 of this series, for additional information.

The blast gate control automatically compensates for changes in cupola restriction and changes in atmospheric conditions, and maintains the flow of a constant weight of air into the cupola.

The usual relation of size of cupola, quantity of iron melted and air supply is shown in Table 11. The diameter of blast pipes for various volumes of air is given in Table 12.

**Table 11.—Air Supply Required for Cupolas**

* The minimum radius of each turn should be equal to the diameter of the pipe. For each turn thus made add three feet in length, when using this table. If the turns are of less radius, the length added should be increased proportionately.

**OPERATING RECOMMENDATIONS.**—Cupolas should be operated on a fixed schedule, with a definite time for lighting, for start of charging, for starting blast, for tapping out and for opening slag hole. The tap hole should be carefully gaged to give desired rate of flow of iron, whether tapping is continuous or intermittent. Blast should be maintained according to established foundry practice. All materials used should be checked and recorded daily. Successful cupola operation depends on the adoption of a standard practice. Variations are necessary only when standard practice can be improved.

**CALCULATING CUPOLA MIXTURES.**—No set rule can be given for calculating cupola mixtures, because of variations in cupola operation. The factors influencing control of some elements are: Blast pressure; volume; moisture and temperature; amount and character of coke used; depth of zone or well.

**Silicon.**—Allow 10% loss under normal conditions. When more highly concentrated Si alloys are added, the loss will be higher. Loss of Si in cast iron is due to oxidation; it is controlled principally by blast pressure. A high pressure produces the maximum, and a low pressure the minimum loss, other conditions being constant.

**Sulphur.**—Allow for 0.03 to 0.05 point increase. The increase of S is controlled principally by the coke used. A low-sulphur coke (0.5 to 0.7%) will produce minimum, and a high-sulphur coke (0.7 to 0.9%) maximum S in the iron.

**Phosphorus** remains practically constant; no allowances need be made.

**Manganese**—Allow for a 20 to 30% loss. Mn loss is due to oxidation. Mixtures containing highly-concentrated Mn alloys probably will show maximum Mn loss.

**Carbon.**—On account of the many factors involved, calculation of total carbon (T.C.) is difficult. Steel additions affect T.C. in cast iron. The character and amount of coke, as well as the characteristics of the cupola, also influence T.C.

**Methods of Calculating Mixtures.**—Assume that a 3000-lb. charge containing 25% steel is sought for heavy machinery castings, composition to be: Si, 1.35–1.40; S, 0.07–0.09;

P, 0.25–0.27; Mn, 0.50–0.55. The following classes of stock are available in the yard:

| | Si | S | P | Mn |
|---|---|---|---|---|
| No. 2 pig-iron | 2.10 | 0.032 | 0.505 | 0.64 |
| Malleable iron | 1.80 | .033 | .165 | .75 |
| No. 1 machinery scrap | 1.90 | .085 | .405 | .60 |
| Steel scrap | 0.30 | .050 | .050 | .50 |
| No. 1 pig-iron | 2.90 | .030 | .530 | .84 |
| Returned scrap, gates, sprues, etc. | | | | |

Bearing in mind the increases and decreases of the elements in melting, the following method of calculation can be used: Draw from the stock piles quantities of the various irons as shown in Table 13. Opposite each iron enter the percentage content of each element as Si, S, etc., expressed as points per lb. Multiply the points per lb. of each element in each lot of iron by the number of pounds in that lot, and enter the product as total points. Divide the sum total points of each element by the total weight of all the lots of iron in the mixture. Add to or subtract from the total points of each element, the gain or loss of that element in melting. The sum or difference as the case may be is the percentage of each element in the iron resulting from the mixture. Note that the gain in S is expressed in points and not in percentage as is the case with the other elements.

A daily record should be kept of all mixtures, on a form similar to Table 13.

**ALLOYS.**—At times it is desired to cast alloy-irons. Alloys of Cr, Ni, Mo, Vn, and Ti can be had in a form for introduction in spout or ladle. High-silicon irons, as silvery iron (8.00 to 10.00% Si) and Bessemer ferro-silicon (12.00 to 15.00% Si), come in pigs and are mixed with the cupola charge when higher Si is wanted than is available from stock piles. Fe-Si alloy (50% and 80% Si), both lump and ground, also is used to increase Si in cast iron. It generally is ground for ladle additions. High-Mn irons, as spiegel (19.00 to 21.00% Mn), in pig form, is added to the charge in the cupola. Fe-Mn (80.00% Mn) in lumps is added in the cupola; the ground is form added to the ladle. These alloys are used when higher Mn is wanted than is available from stock piles. Fe-Si and Fe-Mn may be obtained in briquets which are added in the cupola.

**MELTING LOSSES.**—Melting loss is the difference in weight between iron charged and that recovered in the form of castings, sprues and other scrap. It is due to oxidation of the metal during melting and to a reduction in the silicon and manganese in the iron, also by oxidation. Melting loss varies with class of work and with cupola practice. Table 14 calculated from performances of cupolas, given by Payne, shows the average melting loss in 39 foundries doing a variety of work.

The melting loss frequently appears to be higher than it actually is, due to the weight of adhered sand on the pig iron, sprues, etc., and rust attached to purchased scrap. Moldenke gives the following percentage figures as the average melting loss of the usual

**Table 13.—Method of Calculating Cupola Mixtures**

## Special Types of Cupolas

During the ten years, 1925–1935, remarkable strides were made in increasing the efficiency, flexibility and application of the foundry cupola. A few successful types are described below.

**THE GRIFFIN HOT BLAST PROCESS** was developed by the Griffin Wheel Co., Chicago. The distinguishing feature of the system is the application of the recuperative principle to cupola operation. Cupola gases at about 1700° F., and containing CO are drawn into a duct surrounding the cupola a short distance below the charging door. They are burned in a refractory-lined heating chamber in the presence of excess air bled from the blast line, raising the temperature to about 1800° F. The burned gases pass into either a recuperative or a regenerative preheater and are discharged through a supplementary stack. Blast air from a positive pressure blower passes around and across the ducts conveying the burned gases from the combustion chamber, and thence into the main hot blast pipe to the tuyeres. The arrangement of the Griffin cupola embodies a continuous pouring spout with an inverted weir for front slagging. The efficiency of the hot blast cupola is claimed to be 55%, as compared with a normal efficiency of 37%.

**THE MOORE HOT BLAST CUPOLA** is a development of the hot-blast principle made necessary by individual requirements, and installed by the American Cast Iron Pipe Co., Birmingham, Ala. This comprises 8 vertical pipes in the wall of the cupola above the melting zone. These pipes are of low-silicon, high-carbon, low-phosphorus cast iron designed to resist heat and abrasion of the coke and iron charges. Blast from a bustle pipe around the cupola enters the upper end of the preheating pipes, and passes downward, to enter the cupola at the tuyeres. The blast temperature entering the tuyeres is estimated at 300° F.

**THE POUMAY CUPOLA.** (R. T. Rolfe, Foundry Work and Metallurgy.)—Attempts have been made by means of auxiliary upper tuyeres to attain more effective combustion by burning the CO formed by the reduction of the initial $CO_2$. In the Poumay system, the production of CO in the melting zone is considered advantageous. It aims to induce incomplete combustion in the lower part of the cupola, thus avoiding oxidation. The arrangement of the regenerative tuyeres in the Poumay cupola causes the fractional combustion of CO higher in the shaft to preheat the descending charges, and yield hot metal, with low coke consumption. Poumay states that success or failure depends on the position, arrangement, and number of regenerative tuyeres. He also claims: 1. All useful gases are burned in the cupola below the level of the charging door; 2. Oxidation is reduced to a minimum with resulting low metal loss; 3. Melting is rapid; 4. Sulphur

* Bed charge of iron the same weight as the other charges. † Two blast pipes.

content of metal is reduced; 5. Fuel consumption is reduced. The essential principle of the cupola is a row of main tuyeres and a secondary row entering the cupola at varying heights. The air for the upper, or auxiliary, tuyeres is taken from the main bustle pipe and the volume of air entering each tuyere depends on pressure and resistance.

**THE BALANCED-BLAST CUPOLA.**—The balanced-blast cupola, developed by J. E. Fletcher and patented for use of British Cast Iron Research Assoc. members, differs from the Poumay cupola in that primary control is provided for the lower row of tuyeres. The upper row is proportioned according to predetermined conditions to provide the proper volume of entering air. The main row of tuyeres is placed below the bustle pipe, each provided with hand-adjusted valves. The aperture into the cupola slants down to reduce the velocity of the entering blast. Closing the valves on the main tuyeres raises the pressure of the blast in two or more rows of upper tuyeres. One setting of the main valves is said to be suitable for one particular type of charge, size of scrap, pig iron, fuel, etc. J. E. Hurst reports that on a 54-in. balanced-blast cupola, a coke ratio of 18 to 1 was obtained with an increase in melting rate from 10 to 14 tons per hr.

**Briquetting Foundry Borings.** (A. L. Stillman, *Trans.* A. F. A., xxvi, p. 493, 1917.)—Cast-iron borings charged directly into the cupola have carbon and silicon burned out to such an extent that the product approaches low quality white iron. Briquetting the borings removes most of the objections to their use in the cupola. A series of tests were made at the Baldwin Locomotive Works at Philadelphia, Pa., using the Ronay metal briquetting press to consolidate the borings. The borings were compressed under a pressure of 30,000 lb. per sq. in. into briquettes 5 in. diameter and 7 to 8 in. high, weighing about 28 lb. Their density was about 80% of the normal density of iron. Three test mixtures were made for miscellaneous castings, and three for castings of locomotive cylinders. The regular mixtures in each case were composed of pig iron, scrap and car wheels in varying percentages. The object of the tests was to determine the effect of substituting briquettes for varying percentages of these several constituents. The composition, chemical analyses and strength of castings from the several mixtures are given in Table 16, the charge in each case being 3000 lb. From the foundry point of view, and considering the work for which the iron was designed, the mixtures containing briquettes were as well, if not better, adapted to that work than the regular mixtures. In loading the charge, the briquettes were placed on top so that they would not be subject to heavy impact in charging.

The Southwark Foundry & Machine Co., Philadelphia, has developed an automatic hydraulic press to exert a pressure of 600,000 lb. One of these, installed by Dodge Brothers, Detroit, was followed by installations in other plants operating cupolas and having quantities of borings or chips. A 75-Hp. motor, drives the machine at 18 r.p.m., producing 18 7-lb. briquettes per min. or 3.78 net tons per hr. Borings are fed to the machine from a storage hopper by conveyors. Briquettes are removed from the machine to the cupola charging deck by conveyors. The cost of briquettes so made in 1929 was $1.91 per net ton. Briquettes used are 16.67% of the total melt, being placed on top of each successive charge, followed by the coke for the next charge. The briquette melting loss is slightly under 10%. The briquettes do not disintegrate in the melting zone, many partly melted being found in the bottom drop at the end of the heat. No difference in percentage of good castings made followed the introduction of briquettes.

## The Air Furnace

**THE AIR FURNACE** is a hearth furnace with separate fire box and melting chamber. The flame passes over the bridge wall, through the melting chamber, the gases sweeping

the hearth, and thence to the chimney. The gases partially melt the stock, but principally heat the walls and roof of the melting chamber to incandescence, radiation from which does most of the work of melting and superheating. Fuel and metal are not in direct contact, excepting gases and fine ash carried over. Hence, absorption of sulphur is not as great as in the cupola.

The type of air furnace generally used in gray iron foundries for production of high grade metal, is short, fairly wide and high, and is charged from the end. It is possible to introduce entire cannon, rolls and heavy pieces of scrap. The furnace is built for heavy tonnages, 25 tons being an ordinary, and 40 tons an occasional, charge. Natural draft generally is used, although powdered coal blown in under pressure also is used. Chimney height for natural draft ranges from 60 to 85 ft., 75 ft. being a good average. Good draft is necessary for combustion and to carry the gases to the far end of the melting chamber. Too much draft causes excessive temperatures in flue and chimney walls, and exposes the thin layer of molten iron to oxidation and consequent damage.

Products generally made in the air furnace include gun iron, chilled and sand rolls, steam and gas engine cylinders, and work requiring special physical qualities and great strength.

**Coal Consumption** of the air furnace ranges from 40 to 55 lb. per sq. ft. of grate per hr. At the latter figure the fires are forced, and unless stack capacity is ample, incomplete combustion and considerable waste of fuel result. For example, of two American air furnaces, one, burning 53.5 lb. of coal per sq. ft. of grate surface per hr., melted 3.65 lb. of iron per lb. of coal; the other burned 51.3 lb. of coal per sq. ft. of grate per hr. and melted 2.30 lb. of iron per lb. of coal. The same furnaces, each melting 22-ton heats, and burning 44 lb. of coal per sq. ft. of grate per hr., had ratios of 4.00 and 2.75 lb. of iron per lb. of coal, respectively.

**COMPARISON OF AIR FURNACE AND CUPOLA.**—Moldenke (Principles of Iron Founding) compares the air furnace and cupola as follows: 1. Air furnace iron is stronger and better than cupola iron. 2. With good coal, air furnace iron will be lower in sulphur. Compared with the best cupola practice, the air furnace has no advantage in oxidation; silicon drop in the cupola is 0.20, against 0.30 in the air furnace. The cupola usually is not run on low-silicon mixtures except for malleable castings, with great attention to melting to avoid oxidation. 3. The air furnace permits changing composition of the iron before tapping, an impossibility with the cupola. 4. The air furnace permits reduction of total carbon by addition of steel to the charge, up to 30%. This is not possible with the cupola, in which the steel absorbs carbon, the resulting total carbon in the iron being uncertain. 5. A large tonnage is available in one tap from the air furnace; several cupolas operated at the same time are necessary for the same tonnage. 6. The air furnace can use large heavy pieces of scrap which cannot be handled and melted in the cupola.

## Powdered Coal Furnaces

**THE BRACKELSBURG FURNACE** is a horizontal cylinder, with removable conical ends, giving access for relining and repair. It rotates at 15 ft. per min. in a tilting cradle, tires on the drum engaging power-driven rollers on the cradle. For charging or pouring it may be tilted 50°. The furnace burns 170-mesh powdered coal, in a burner directed into the end of the furnace when in melting position. The air pressure is 10 to 13 in. of water. A stack carries combustion products and ash out of the building. Recuperators may be used with this furnace. The advantages claimed are temperatures of 2700° to 2850° F., capable of advance to 3100°, with a preheater; rotation of the melting charge promotes thorough mixing, uniformity, and high quality. The ratio of air to fuel on a 2-ton furnace is given as 3 to 1 when cold, increasing to 5 to 1. A ratio of 6 to 1 is claimed for larger furnaces.

**THE SESCI FURNACE**, developed by Societe des Entreprises Speciales de Chauffage Industriel, Paris, is a rotating unit using a powdered fuel. The cylindrical furnace, of steel plates, angles, cast steel rings and end plates, rotates on rollers, driven at one end by a reversible electric motor through a chain drive. Rotation in either direction is from 20 to 360°. The fuel is 200-mesh powdered coal, fed by a screw distributor into a hot air pipe. The fuel, intimately mixed with preheated air, enters the burner, and thence the end of the furnace. Hot gases from the furnace preheat the air to 1100° F. An operating economy of 20% due to preheating is claimed. A melting temperature of 3270° F. is attainable, which permits pouring metal at 2900°. Fuel consumption is given as 16% for pig iron of 2.5% C, 1% Si. An English operator of several Sesci furnaces uses bituminous coal at the start of the heat, and changes to anthracite when the temperature of the entering blast is 390° F. Four furnaces supply 22 tons of iron, using an 80% scrap charge. A 5-ton furnace melts in 110 min. while 10-ton furnaces require 2 hr. The capacity of the battery of four furnaces is 80 tons per 8-hr. shift. The high temperature, and, in effect, superheating, together with production of low carbon iron from steel scrap by control of carbon, recommends this furnace for close chemical requirements.

## The Electric Furnace

**THE ELECTRIC FURNACE** for melting gray iron permits closer control of analyses and superheating; it also allows small heats to be made quickly and intermittently. Direct and indirect arc-type furnaces are used, both to melt down from cold stock and to refine molten metal from the cupola. Availability of inexpensive scrap, as borings and turnings, power rates and other economic factors influence the use of electric furnaces. The main advantages of electric furnace melting, according to L. J. Barton (Refining Metals Electrically) are: *a.* Superheating: lowers percentage of lost castings; improves appearance and solidity of castings; decreases size of heads, due to greater fluidity of metal; saves iron and labor by decreasing pig and ladle skulls; causes cleaner metal to enter the mold, as impurities tend rapidly to clear themselves from fluid iron, resulting in lower losses from sand and slag spots; gives iron of higher quality and strength. *b.* Refining: deoxidizes the iron, an advantage as great as if steel were being cast; lowers sulphur to any desired point, thus requiring less manganese. *c.* Composition: iron of analyses of absolute regularity can be made; low phosphorus irons can be melted and easily cast; large proportions of steel can be used to give irons of widely varying characteristics. *d.* Economic: pig iron can be eliminated from the charges; scrap, such as borings, may be used with insignificant losses; foundry is independent of quality of coke supply; large pieces impossible of cupola melting may be charged.

**Costs.**—N. L. Turner (*Trans.* A.F.A., vol. xxxviii, p. 749, 1930) reports on the operation of a 3-ton, direct-arc furnace utilizing cast-iron borings, shop scrap and steel clippings with alloy additions, with a cost of iron at the spout of $23.71 per ton. Of this cost $11.32 covers metal and alloys; $1.14 labor; $5.25 power; $2.09 electrodes; $0.60 refractories; $1.13 melting loss. The remainder covers water, laboratory investment and depreciation. The metal is poured into stove plate of comparatively high C and Si content.

**Reclamation of Sheet Scrap Material** by a plant producing gray iron castings is a factor recommending the electric furnace. Edwin Bremer (*The Fdry.*, Nov. 15, 1930) describes the application of a rocking type, indirect-arc furnace, utilizing soft steel scrap of 3 to 4% Si. A high grade gray iron is made by treating the charge in the furnace with petroleum coke to increase C. A wide range of C and Si analyses is possible. Tests of the castings range from 23,000 to 40,000 lb. per sq. in. tensile, with Brinell from 163 to 202.

**High Quality Electric Furnace Castings.**—An example of the use of the electric furnace induced by demand for higher quality is provided by H. E. Bromer (*Trans.* A.F.A., vol. xxxix, p. 585, 1931). A 3-ton direct-arc furnace operates in duplex or independently, as the character of castings demand and operating conditions permit. In duplexing, the electric furnace charge is a bath of 15,000 to 18,000 lb. from periodic taps of the cupola. Approximately 1 1/2 hr. after the cupola is in blast, the electric furnace is tapped; up to 1200 lb. of metal are taken out every 5 to 6 minutes. Cupola metal is charged intermittently into the electric furnace. Operation is continuous, the electric furnace acting as a refining and superheating medium for the cupola.

For restricted operation, the electric furnace melts cold stock, comprising cast-iron borings, cast scrap and steel scrap. Power consumption for continuous cold melting averages 540–550 kw-hr. per ton; graphite electrode consumption slightly over 12 lb. per ton. Refractory life, while duplexing, was a total of 800 tons of metal melted before roof was replaced; 1204 tons were melted with the side walls replaced at the same time. Average figures are 600 tons for a roof and 1000 tons for side wall linings.

The main factor in the operation of this furnace was the high quality and uniformity of automotive castings attained. Average tensile strength of unalloyed iron was approximately 40,000 lb. per sq. in. on test specimens machined from 1 1/4 in. round bars. The average for low Ni–Cr iron was practically the same, while high Ni-Cr iron showed average tensile strength of 45,000 lb. per sq. in.; a molybdenum iron averaged 50,000 lb. per sq. in. With electric furnace iron, variation in Brinell hardness taken at various points on cylinder bore, on borings and on flanges varied only approximately 15 points. Impact tests showed the electric furnace iron to have approximately twice the impact strength of cupola iron of similar analysis made for a similar class of castings.

**THE ACID PROCESS** of melting gray iron in the electric furnace offers only the qualities of superheating. It is unable to desulphurize or deoxidize by the use of slag baths, its power of eliminating bases being a function of its silicon. The regularity of composition may be considered as fair only, due to rapid changes of Si in the metal, especially at higher temperatures. It offers certain economic advantages of cheapness, and ability to use certain classes of scrap inapplicable to cupola melting. Its use is limited, and there seem to be no points which should warrant any great increase. For regular operations on iron, Barton does not recommend the acid furnace, the basic process offering far greater advantages.

## 4. CONDITIONS AFFECTING QUALITY OF CASTINGS

**HEAT TREATMENT OF GRAY IRON.**—(J. W. Bolton, *The Foundry*, March, 1933.) A knowledge of graphitization and reactions of metalloids is prerequisite to intelligent heat treatment of cast iron. For maximum softness the temperature of pearlitic cast iron must be carried above the transformation range (1325° to 1340° F.), and cooling through and to, say, 200° F. below this range must be slow. Such treatment produces a material composed almost wholly of ferrite and graphite. To harden, it is necessary to heat considerably above the transformation point and to quench rapidly.

When cooled rapidly or chilled, the cementite-austenite structure is shown. Irons of this structure, called white irons, are intensely hard as cast. Mottled irons lie between white and gray irons. They contain both cementite and graphite, as well as austenite (or at room temperatures) martensite or pearlite. To soften such irons usually requires an annealing temperature higher than is needed for straight gray iron.

Black graphite flakes, which are soft and non-tenacious, weaken the matrix of the iron. They are one of the structural features that distinguish gray iron from steel. The amount, size and distribution of graphite flakes are major controlling factors determining many physical properties of gray cast irons. Control of graphite is important.

A pearlitic matrix is characteristic of most gray irons. Alternate lamellæ of cementite and ferrite, and the general resemblance of this structure to pearlite in steel may be noted in micrographs. The ferrite is similar to that in pure iron and low-carbon steel. Martensitic structure is obtained by proper quenching.

The foregoing statement of the principles underlying heat treatment of cast iron has been confined largely to rather pure iron-carbon alloys. Commercial cast irons are alloys of Fe, C and Si, plus Mn, P, and S, and in many cases *alloying* elements, as Ni, Cr, Mo, etc. In some cases the proper use of alloys facilitates heat treatment by quenching. Lowering of critical range, some stabilization of carbides, and lowering of critical quenching speeds are definite advantages that frequently result in easier manipulation, less drastic treatment, and probability of greater toughness in the finished product. On the other hand, carbide stabilizers as chromium and molybdenum, may make annealing difficult. The influence of the various elements on heat treatment is summarized below:

**Silicon** in cast iron may range from below 1% to possibly 3%. It is a graphitizing element. For a given section the amount of graphitization, *i.e.*, the relative percentages of graphite and combined carbon, can be controlled by adjustment of Si. Si also lowers C required for the eutectic, changes the pearlitic transformation range, and in other ways modifies the properties of the iron.

**Sulphur, Phosphorus,** and **Manganese** may be neglected, as regards heat treatment, except that in sufficient amounts, Mn depresses the critical range.

**Nickel,** in amounts up to slightly over 1%, has a mild graphitizing action and does not interfere with annealing. It lowers the critical range and decreases critical quenching speed. Lowering of the critical point by nickel is so marked that at from 4 to 8% Ni, cast iron will be largely martensitic, and at 18 or 20% Ni it is largely austenitic.

**Chromium** is a carbide stabilizer, tending to inhibit graphitization. It is said to raise transformation range, but to decrease critical quenching speed.

**Molybdenum** is a carbide stabilizer, lowers transformation range and decreases critical quenching speed.

**General Precautions** in heat treating of cast iron must be observed, as follows: 1. For good results, the original castings must be close grained material, of say 2.70 to 3.20% C, with a largely pearlitic matrix, *i.e.*, combined carbon, 0.50 to 0.70. Coarse, open-grain irons do not heat treat well. High-carbon, high-silicon irons should be avoided. 2. All cast irons are relatively non-ductile. Cold castings, particularly complicated shapes, placed in a hot furnace are likely to crack. Preheating to 500° or 600° F. is advisable. 3. Drastic quenching treatments are to be avoided. Quenched castings must be drawn to maintain toughness. 4. In quenching treatments, long holding at high temperature will cause trouble.

The principal commercial heat treatments applied to gray cast irons are: 1. Normalizing, aging, or low temperature annealing, to relieve internal stresses. 2. Dead or softening annealing to increase machineability. 3. Quenching and drawing to increase hardness and wear resistance. 4. Nitriding. For chilled or mottled irons a fifth type of annealing, *Chilled iron anneal*, is used.

**Low Temperature Anneal.**—Many castings, particularly those of uneven section, have internal stresses, which, if not relieved, cause warping and, in extreme cases, cracking. In precision work, earlier practice allowed the castings to age from a few days up to several months. This practice took time and was not always effective. Other castings are used at fairly high temperatures and must maintain their dimensions under operating conditions.

Low temperature annealing or quick aging to remove internal stress comprises heating to about 900° F., holding from 1 to 8 or 10 hr., and cooling slowly to below 450° F., in the furnace. The metal is made plastic enough to relieve internal stresses without entering the temperature range of graphitization. In most close-grain irons graphitization at 900° F. is slow, hardly appreciable over a few hours. With open-grain irons it may be desirable to drop the temperature to 800° F. This type of quick aging causes little change in the physical properties of the metal. To obtain a slight softening as well as stress relief the temperature may be raised to 1000° F., or even to 1150° F., depending on time and on amount of softening desired. Softening usually results in a slight loss of tensile strength.

**Softening Anneal.**—Dead or soft annealing of gray iron requires heating above transformation point, holding long enough to allow complete penetration of temperature, and cooling slowly to well below the pearlitic transformation. Annealing temperature usually is about 1450° F., followed by slow cooling to 900° F. or under. In the presence of certain alloys it may be necessary to increase the temperature, time, or both. Dead annealed cast iron is soft, usually about 120–140 Brinell, depending on total carbon and Si. In presence of alloys, hardness may be somewhat higher. Dead annealed cast iron is easily machined. Its strength usually is 10 to 25% lower than that of the original cast metal. Too high annealing temperature, or too long annealing time, or both, may cause graphite grain growth, with consequent detriment to properties of the metal.

**QUENCHING TREATMENTS.**—Completely chilled irons usually require higher annealing temperatures (1600° to 1750° F.) than gray irons. Several hours may be required to fully break up the cementite. Castings with small chilled spots in fins, small sections, etc., often cause trouble. To eliminate hard spots it is necessary to anneal at 1450° F., and sometimes at higher temperature. The correct temperature and time is a matter of experiment. An anneal with slow cooling will break down the desirable pearlitic matrix, resulting in softness and loss of strength in the body of the casting. No definite rules can be given for retention of maximum physical properties, but it may be necessary to follow the high temperature period with a quench and draw. If a mottled iron or a white iron be properly treated, it is possible to produce so-called semi-malleable. For semi-malleable, the maximum annealing temperature may be 1700–1750° F. After soaking 3 hours, the castings are cooled in the furnace to about 1400° F. They then may be air quenched, oil quenched and drawn, or cooled in the furnace, depending on result desired.

If a low-carbon, low-silicon iron (2.00–2.50% C, 1.00–1.50% Si) is used, it is possible to produce material well over 60,000 lb. per sq. in. tensile strength, or even over 75,000 lb. per sq. in., and also to obtain some ductility. Brinell hardness may be from 150 up, depending on the iron and on the quench used.

The high temperature anneal, and in mottled iron, the presence of graphite flakes as cast, leads to carbon formations intermediate between the flakes of gray iron and the nodules of true malleable.

Quenching treatments usually comprise heating to about 1500° F., holding just long enough for complete heat penetration, and quenching, usually in oil. Air quenching usually is so slow that instead of hardening, actual softening of metal may occur. Water quenching often is too drastic and the metal may be made excessively brittle. The danger in quenching cast iron is graphitization. If the treatment produces more graphite and less combined carbon, the desired hardness will not be attained. The presence of an increased amount of graphite often both embrittles and weakens the metal.

**Precautions and Procedure** that will give best results in quenching treatments are: Metal must be close-grained, reasonably low in C and Si. Sometimes the addition of so-called carbide-forming elements, Cr and Mo, is advantageous, tending to prevent excessive graphitization during heating and quenching. These, with Ni, are said to lower critical quenching speed. As a rule, strength and particularly toughness of gray cast iron is impaired by quenching. The original strength and toughness is regained or exceeded by proper drawing or tempering. Drawing above 350° F. decreases hardness and increases strength and toughness. Both usually are regained fully by drawing at 500 to 600° F., and commonly are increased considerably by drawing to as high as 1000° F. Strength and shock resistance may be increased as much as 50%. Hardness is greatest in the as-quenched condition. It decreases progressively as drawing temperature increases beyond 350 or 400° F., and is not fully lost until drawing temperatures are quite high. Thus, an iron 2.70% C, 200 Brinell, in the as-cast condition approaches 500 Brinell when quenched in oil from 1500° F. When drawn at 1050° F. for 2 hours, it still retains about 275 Brinell.

The usual range of hardness obtained by treatment of machinable castings is 400 to 500 Brinell. Properly quenched and drawn cast iron has a fine, almost silky, grain, much lighter in color than the fracture of regular gray iron. It has excellent wear resistance, both in metal-to-metal wear and under mildly abrasive conditions. Heat-treated cast irons retain the resistance to galling and seizing characteristic of regular gray irons.

**NITRIDING** sometimes called ammonia hardening, has been applied successfully to special cast irons. The process comprises heating for 2 1/2 to 4 days at 900 to 1000° F. in an atmosphere of anhydrous ammonia. The cast iron commonly used contains about 1.5% Cr, 1.5% Al, and total C of 2.50 to 2.75%. It is claimed that if V is added Al can be eliminated. Cast irons of this Cr and C content are quite likely to air harden. The usual practice is to anneal before machining. The castings then are hardened, drawn, and nitrided. Surface hardness equivalent of 800 to over 900 Brinell is claimed.

**HARDENED CAM CASTINGS** should be made of so-called semi-steel, containing approximately 15% steel. Si should be adjusted to section of casting. Assume the cam to be a plain casting approximately 1 in. thick and to be machined. The recommended composition is: T.C., 3.2; Si, 1.0–1.2; Mn, 0.5–0.7; P, 0.15–0.2; S, under 0.08. To harden, the cam should be warmed throughout to 300° F., rapidly heated to 1530–1550° F., and held at this temperature for 30 min., or until uniformly heated. It is then carefully lowered into water at 80–90° F., cooled to about 300° F., and then immediately placed in hot oil at 400° F. It is held at 400° for 30 min. to 1 hr., to remove strains and avoid cracking. This treatment gives a Brinell hardness of 500. If greater hardness is required, the cam is quenched in clear cold water, and while still steaming, is placed in oil at 350° F., for 30 min. This treatment tends to cause warping, and unless skillfully done will cause cracking. A Brinell hardness of 400 to 450 may be obtained by quenching in cold oil, withdrawing from oil when the casting is at about 300° F. This treatment will avoid warping.

## 5. STEEL CASTINGS

**DEFINITION.**—Cast steel is an alloy of iron C, Mn, Si, and other elements, which is malleable, at least in some one range of temperature, and is cast into an initially malleable mass, or is capable of hardening greatly by sudden cooling, or is both so cast and so capable of hardening. Castings are solidified from the molten state in molds.

**USES.**—Cast steel products range in section thickness from 1/4 in. to 4 ft., and weigh from a few ounces to many tons. The extreme size recorded (1937) is over 200 tons. Within the extremes of size and weight an infinite variety of shape and dimension is possible in cast steel. A classic example is a unit casting embodying a locomotive and tender frame complete with integral cylinders, cast in one piece with an overall length of 65 ft.

**CLASSES.**—Steel castings mainly may be classified as carbon cast steels and alloy cast steels. Plain carbon cast steels (C. H. Lorig and C. E. Williams, *Proc.* A.S.T.M., vol. xxxii, Pt. 2, p. 114, 1932) contain 0.50 to 0.90% Mn, 0.20 to 0.70% Si, and 0.05%, or less, of S and P. Carbon cast steels are divided into three grades: regular, from 0.22 to 0.35% C; low carbon, less than 0.22% C; high carbon, containing more than 0.35% C.

**SPECIAL ALLOY STEEL CASTINGS.**—(R. A. Bull. A.S.M.E., 1932.) Many combinations of alloys commonly used are possible by introducing as many as eight different elements. Besides the range of properties attainable through these elements, a variety of heat treatments, varied with each of the different alloy additions is possible. For example, satisfactory results from steel castings may be attained when the metal contains elements as low and as high as the following: C, 0.05–3.00%; Mn, 0.05–4.00%, and 10.0–15.0%; Si, 0.08–3.00%; Ni, 0.15–35.00%; Cr, 0.15–30.00%. The interval between the low and the higher range of manganese represents unexplored territory. The lower range materials are classified as pearlitic or sorbitic and those in the higher range as austenitic manganese steel.

The proportions of Ni and Cr represent variable quantities added either for improving structural properties, or for specific avoidance of corrosion under extreme conditions of temperature and corrosive elements. The complexity of alloy cast-steel properties and applications is indicated by the fact that 15 different heat treatments may be applied in one day to the output of a foundry making numerous alloy steels. These vary from full annealing, to normalizing, drawing, tempering, quenching in different mediums, and do not include such specialized treatment as carburizing or nitriding. In alloy cast-steel production the proper application of heat treatment is a vital consideration.

**MELTING MEDIUMS.**—Cast steel may be produced in crucibles, converters, open-hearth and electric furnaces. Since 1925, but small quantities of steel castings have been made in the crucible and converter. The choice of the open-hearth or electric furnace for plain carbon steel depends on quantities. Satisfactory special alloy castings can be made from the open-hearth, but the electric furnace, due to flexibility and small size requirements, generally is used for alloy-steel castings.

**The Open-Hearth Furnace** for steel castings differs mainly in size from that used for structural steel ingots. The metal melts in a chamber into which flame from gas, oil, or in some cases, coal, is applied directly to the bath. Metal is charged through along one side of the furnace. Metal is tapped through a centrally located outlet on the opposite side. The roof arches transversely to the length of the furnace. Roof and sides are of highly refractory brick to withstand temperatures of 3000° F. or more.

Steel foundry open-hearth furnaces range from 10 to 40 tons capacity. A few are in operation as low as 5 tons, and as large as 60 tons. In acid furnaces, the lining is silica brick, with a 1- to 2-ft. bottom of silica sand under the bath. Basic linings are of magnesia brick, with a bottom of magnesite.

In acid melting, less than half the charge is pig iron; the remainder is steel. Oxidation of carbon in the charge is due to the $SiO_2$ and $Fe_2 O_3$ of iron ore which is added to increase this action. Oxidation of manganese and silicon raises the temperature. Sulphur and phosphorus are not reduced, and the use of scrap is limited to grades which do not have these elements in excess. In operation, carbon is removed below the desired final product and the total raised by additions of ferromanganese and ferrosilicon.

Basic melting is used for products in which high percentages of P and S would be deleterious. Additions of limestone with a large percentage of $CaCO_3$ provide the chemical reaction with Mn on P and S. In both basic and acid practice, ladle additions will accurately control the chemical elements.

**The Electric Furnace** uses both acid and basic linings. The character of available scrap influences the choice of lining. The acid process, due to speed and economy, is used whenever possible. The basic lining is essential in production of manganese steel and, due to its deoxidizing features, is of value in recovering costly alloys, as Cr, Mn, V, Mo and Ni. A melt may be held in the basic furnace for a longer period without change in regularity of composition.

The acid process is favored for plain carbon steel castings. Higher power input is possible with shorter melting period than in the basic furnace. Considerations of lining cost, lower electrode consumption and other factors are important.

The arc type furnace is commonly used. For special alloys, and also to make heat- and corrosion-resistant alloy castings, electric induction furnaces up to 1000 lb. capacity are used.

## Carbon Steel Castings

**LOW-CARBON STEEL CASTINGS** (C. H. Lorig and C. E. Williams, *Proc.* A.S.T.M., vol. xxxii, Pt. 2, p. 114, 1932), according to the previous classification, do not respond to heat treatment except in refinement of grain structure and improvement in ductility. They range in tensile strength from 42,000 to 70,000 lb. per sq. in., with an elongation from 15 to 30%. The carbon content makes this grade of casting particularly applicable to electrical equipment. Such steel also is used for annealing containers, ladles and other heavy parts subjected to high temperatures. Higher carbon grades are more suitable for structural purposes.

**REGULAR-CARBON CAST STEEL.**—Plain carbon steels, 0.22 to 0.35% C, comprise the largest portion of steel castings made. Tensile and other strength properties of plain carbon castings may be varied over a wide range by proper heat treatment. Tensile strength ranges from 60,000 to 80,000 lb. per sq. in.; elongation from 20 to 30%; reduction of area from 20 to 40%. To develop mechanical properties, castings should be heat treated by quenching and drawing if design permits. After such treatment, regular carbon steel castings often equal those of some special annealed alloy steel. Endurance properties developed by Prof. H. F. Moore show a ratio from 40 to 50%. The magnetic properties of regular carbon steel permit its use in moving parts of electrical equipment. Tensile strength of regular carbon cast steel increases to a maximum at 400° to 600° F., while elastic limit and yield point decrease. A limited number of tests show only slight embrittlement at low temperatures. This grade of steel castings is used widely in railroad service, machine building, automotive industry, decorative and ornamental work, and, to a limited extent, in chemical and refinery service at high temperatures and pressures.

**HIGH-CARBON CAST STEEL**, 0.40 to 0.90% C, develop superior properties when annealed or quenched and drawn. Tensile strength varies from 70,000 to 120,000 lb. per sq. in.; elongation from 3 to 20%; reduction in area from 8 to 40%. High-carbon steel castings, properly heat treated, may be used where high strength and toughness are desired, as in roll and die tool manufacture, machine tools, automotive, contractors' and railway equipment.

**MEDIUM MANGANESE CAST STEEL.** (Lorig and Williams, *Proc.* A.S.T.M., vol. xxxii, Pt. 2, p. 143, 1932.)—Additions of small percentages of Mn do not constitute alloy steel according to foundrymen's interpretation of such terms. John Howe Hall describes these lower Mn steels as divided into pearlitic Mn, intermediate Mn, and high Mn steel. Hadfield, or regular, Mn steel contains 12% or more Mn and more than 1% C. Steels of low Mn are used where high strength with great toughness is essential. The tensile strength and elastic limit increase slowly with Mn, while elongation and reduction of area decrease. According to Zuege, cast steels with 1.35 to 1.55% Mn and 0.27 to 0.37% C, have a tensile strength, 95,000 lb. per sq. in.; elongation, 20% in 2 in.; reduction in area, 40%, when normalized at 1650° F. The same steel normalized at 1650°, drawn at 1250° F., shows 85,000 lb. per sq. in. tensile strength; 24% elongation; 45% reduction of area. A slight decrease in both C and Mn increases toughness but lowers strength.

The customary range of analysis of medium Mn cast steel that can be treated by quenching in oil or water and drawing, or normalizing and drawing, is: 0.20 to 0.40% C; 0.20 to 0.50% Si, and 1.10 to 2.00% Mn. When properly heat treated, these grades are ductile, with high tensile properties and resistance to abrasion.

Addition of Mn to Ni steels, using 1.00 to 1.75% Ni and 1.00 to 1.50% Mn, with C from 0.30 to 0.40%, gave tensile strength, 80,000–90,000 lb. per sq. in.; elongation, 18–23%; reduction of area, 28–33%. These values are increased by proper heat treatment.

**NICKEL CAST STEELS** (Lorig and Williams, *Proc.* A.S.T.M., vol. xxxii, Pt. 2, p. 161, 1932).—Cast steel with C, 0.10 to 0.60%, and Ni, 0.5 to 5.0% are characterized by high strength and elastic limit, ductility and resistance to impact. Tensile strength may be 75,000 to 110,000 lb. per sq. in.; elongation, 7 to 26%; reduction of area, 5 to 50%, depending on heat treatment followed.

To develop high impact and fatigue resistance in steel containing 0.20% C (max.), 2.0% Ni (min.), 0.60 to 0.90% Mn, 0.15% Si (min.), the following heat treatment is adopted: Heat 2 hr. per 1-in. thickness at 1750° F., with air cooling; normalizing 1 1/2 hr., per 1-in. thickness at 1500–1550° F.; draw at 1100 to 1250° F., with furnace cooling. Such treatment gives tensile strength 75,000–85,000 lb. per sq. in.; elongation, 23 to 32%; reduction of area, 45 to 65%.

Low-carbon nickel steels are used in many locomotive castings to resist impact and fatigue, and in mining and excavating machinery, marine and rolling mill service and for bridge castings.

**NICKEL-MOLYBDENUM CAST STEEL.**—The hardening tendencies of Ni steel are increased by small quantities of Mo, (Lorig and Williams, *Proc.* A.S.T.M., vol. xxxii, Pt. 2, p. 163, 1932). Such steels require normalizing and tempering to develop best impact and ductility values. Castings with 0.25 to 0.30% C, 0.60 to 0.80% Mn, 1.25 to 1.50% Ni, 0.30 to 0.35% Mo, show tensile strength 85,000 to 90,000 lb. per sq. in.; elongation, 22 to 25%; reduction of area, 45 to 50%. Ni-Mo steel castings are recommended for service at high temperatures.

**MOLYBDENUM CAST STEEL.**—Molybdenum increases the tensile strength of heat-treated steels containing more than 0.30% C. Its high yield point at elevated temperatures is characteristic. Molybdenum-steel castings are used in rolls, turbine housings, and where high tensile strength is required. Due to its air-hardening characteristic molybdenum gives good results in large castings which cannot be quenched in liquid, but which must have hardness to resist abrasion.

**MANGANESE-MOLYBDENUM CAST STEEL.**—Heat-treated Mn-Mo cast steels with 0.20 to 0.40% Mo, 1.0 to 1.75% Mn, 0.30 to 0.40% C, range from 90,000 to 160,000 lb. per sq. in. tensile strength; elongation, 14 to 30%; reduction of area, 40 to 60%. The Mn-Mo steels have a marked tendency to air harden. Unless properly heat treated, ductility and toughness are decreased.

**CHROMIUM-NICKEL CAST STEELS** (Lorig and Williams, *Proc.* A.S.T.M., vol. xxxii, Pt. 2, p. 177, 1932), with 0.28 to 0.60% C, 0.60 to 0.87% Mn, 0.66 to 1.60% Cr, and 1.00 to 2.85% Ni, with various heat treatments, range from 100,000 to 202,000 lb. per sq. in. tensile strength; elongation, 6 to 23%; reduction of area, 10 to 52%. The distinct advantage of this class of alloy steel castings is the improvement in properties made possible by proper heat treatment. Zuege reports normalized and drawn Cr-Ni steel at slightly higher yield points and tensile strengths than normalized Mn carbon steel, but with lower ductility. Rapid quenching emphasizes the hardening and strengthening effects of Cr and Ni. Cr-Ni steel may be hardened to a higher Brinell than Mn carbon steel. Fatigue resistance is high, and Cr-Ni cast steels give satisfactory strength at high temperatures. They have good mechanical properties which may be developed by simple annealing. Proper heat treatment, however, improves these properties. Medium carbon Cr-Ni steel gives excellent service under wear. Castings are adapted to use as grousers or tracks for caterpillar treads, chain belt parts, rolling mill rolls, oil refinery and other machinery. The resistance of these steels at high temperature and their corrosion-resistant properties adapt them to use in chemical and refining industries. The addition of Mo to Cr-Ni steel does not affect its mechanical properties, but improves machinability and develops air-hardening characteristics.

**PEARLITIC STEELS** (Fred Grotts, *Proc.* A.S.T.M., vol xxxii, Pt. 2, p. 197, 1932).—Cast medium pearlitic steels, when normalized, consist principally of pearlite. They contain a small amount of special material as Ni or Si dissolved in the ferrite, which may be combined with carbon as cementite, as a double carbide of iron and of the special element, or may be partially in solution in ferrite with Mn, Cr, W, V, or Mo. Pearlitic steels have higher yield point and ductility and greater hardness than plain carbon steel. Pearlitic carbon steels containing 0.40 to 0.50% C are used in wheels, rails, cutting tools, gears, tractor shoes, dies, etc.

Adding small quantities of Mo to pearlitic steels increases yield point and toughness. Average properties of 0.30–0.40% C pearlitic steel with 0.30–0.40% Mo, fully annealed, normalized and drawn, are: Tensile strength, 83,200 lb. per sq. in.; yield point, 58,100 lb. per sq. in.; elongation, 21%; reduction of area, 33%.

Adding 0.10 to 0.20% V gives average properties of: Tensile strength, 91,500 lb. per sq. in.; yield point, 58,500 lb. per sq. in.; elongation in 2 in., 28.5%; reduction of area, 50.5%.

From 0.75 to 1.00% Cr added to the same range of carbon in pearlitic steel results in: Average tensile strength, 95,000 lb. per sq. in.; yield point, 55,000 lb. per sq. in.; elongation in 2 in., 18%; reduction of area, 31%. Additions of Cr increase hardness and are recommended for castings subject to abrasion, to water corrosion and high operating temperatures.

While Mn is added as a deoxidizer, it also alloys in pearlitic steels. Medium Mn pearlitic steels contain 0.30 to 0.40% C, and range from 1.05 to 3.00% Mn. Tensile strength range, 80,000 to 117,000 lb. per sq. in.; yield point, 40,000 to 65,000 lb. per sq. in.; elongation in 2 in., 18 to 32%; reduction of area, 31 to 60%. After drawing, medium Mn steels should be air cooled and sometimes quenched. Pearlitic Mn steels have low yield point and impact values in full annealed condition. These properties are improved by the addition of other elements such as V, Mo, Zr, etc.

**CORROSION-RESISTANT STEELS** (Jerome Strauss, *Proc.* A.S.T.M., vol xxxii, Pt. 2, p. 213, 1932) are available to resist attack of polluted atmosphere, natural water, sea water, crude petroleum and other chemicals at atmospheric and elevated temperatures, air and furnace gases and molten salt and metals. They are alloys of iron and chromium which with the introduction of C, Si, S, Mo, W, Ti, V, and Ni acquire specific properties for designated purposes. For a given content of C, corrosion resistance increases with Cr. Finely divided sulphides sometimes are added to improve machinability, while Ni up to 2% reduces grain size, improves shock resistance and slightly increases corrosion resistance. Si up to 2% improves casting qualities and adds to corrosion resistance.

Cr steels resist well oxidizing acids, and gases, and sulphur-rich gases, at high temperatures, but are unsuited to high stresses at high temperatures, or to numerous and sudden variations in stress or temperature. High Ni-Fe-Cr alloys are unsuited to sulphur-rich gases at high temperature, but may be satisfactory at moderate temperatures with reduced sulphur compounds. They are valuable for resisting great stress at high temperature and sudden changes in stress and temperature. Some of these alloys are almost immune to oxidizing acids and quite resistant to $H_2SO_4$, while others show oxidation resistance to a greater degree than plain Cr steels. Practical tests, under severe conditions, indicated prior to 1930 that a medium-carbon alloy containing Si, with about equal proportions of Fe, Cr, and Ni was the most satisfactory as regards strength and stability.

The production of special alloy, corrosion-resisting castings is highly specialized. The user should consult foundries qualified to advise as to analyses, methods of manufacture and treatment.

**AUSTENITIC OR HADFIELD'S MANGANESE-STEEL** (John Howe Hall, *Proc.* A.S.T.M., vol. xxxii, Pt. 2, p. 238, 1932) contains 10.00 to 14.00% Mn. It is toughened and softened by quenching in water from high temperature, is non-magnetic and becomes intensely hard if cold worked. It is made either in the basic electric furnace, or by mixing in a ladle 80% ferro-manganese and low-carbon steel from the open-hearth or Bessemer converter. As cast, Mn steel castings are brittle. Heating to 1900–1940° F. and quenching in cold water makes them strong and tough. Tensile strength ranges from 80,000 to 110,000 lb. per sq. in.; elongation in 2 in., 15 to 35%; reduction of area, 15 to 35%. As cast, Brinell hardness is slightly over 200; this is reduced slightly by heat treatment, and increased by cold working. Local pounding may raise hardness to over 500 Brinell. In services subject to heavy wear, increase in hardness is a valuable property, and recommends austenitic Mn steel for frogs, crossings, lining plates of grinding mills, steam shovel teeth and lips, delivery buckets, crane wheels, gears, pinions, racks, etc. The toughness from cold working makes Mn steel castings wear-resistant in a ratio of 20 to 1 as compared with many other materials. Hardening under severe cold work renders machining difficult, and practically all machining operations are performed by grinding.

**DESIGN FOR STEEL CASTINGS** (F. A. Lorenz, *Proc.* A.S.T.M., vol xxxii, Pt. 2, p. 58, 1932).—Steel castings may be adapted to a wide range of work by proper application of fundamental design principles. The range increases as the designer works with the foundry. The designer should initiate co-operation, and consult with the foundry to effect adjustments that will reduce cost and increase life and economy of the casting.

Steel castings are poured at temperatures above 2800° F. The contact of metal with the chilled surface of the mold instantaneously forms a skin of solidified metal. Steel as it solidifies forms crystals, which formation involves contraction from all directions toward the center. The center, solidifying last, continues to supply the demands for metal and a shrinkage cavity may result. Adequate feeding and the location of risers to supply heavy sections with surplus metal is advisable.

The point of junction between light and heavy sections and the progressive freezing of heavy sections requires provision for the surrounding sand to carry away heat. Ample radiating surface and suitable radii between adjoining sections are recommended. A uniform rate of cooling will avoid cooling strains. Deep pockets, with sharp interior corners, produced by bodies of sand of insufficient area to conduct away heat of the surrounding metal should be avoided. Adequate fillets or the coring of heavy sections near adjoining members of a casting avoids concentration of cooling stresses. Abrupt changes in cross section invariably are to be avoided.

The linear shrinkage of steel as it cools causes an actual movement of the casting in the sand. Projections, flanges, bosses or brackets which prevent or impede this contraction may, by a proper use of cores, special sand mixtures and other precautions, be rendered harmless in their effect on the finished casting.

**FACTORS IN STEEL CASTING DESIGN** (Steel Founders' Society of America).—1. **Shrinkage Allowance for Patterns,** varies according to design of casting and temperature of metal poured, as well as the restraint of the mold caused by projecting lugs, cores, etc. Owing to this variation in shrinkage of steel when cooling in the mold, patterns may have different allowances for different dimensions. Shrinkage of open-hearth cast steel varies from $^1/_{16}$ in. to $^1/_4$ in. per lineal ft.; the average is taken as $^3/_{16}$ in. Shrinkage of both carbon and alloy electric cast steels, except high Mn, varies from $^1/_8$ in. to $^3/_8$ in. per lineal ft. High Mn steel shrinks from $^3/_{16}$ in. to $^7/_{16}$ in. per lineal ft.

2. **Uniformity of Section.**—Thickness of section should be as nearly uniform as possible throughout. When possible, changes in section should be made with a gradual taper, rather than abruptly; if this is impracticable, ribs should be used intelligently. Uneven shrinkage between heavy and light sections causes the metal to tear, results in shrinkage cavities, or gives rise to directional or dendritic crystals in the metal that do not promote high strength. A minimum of bosses, of the minimum thickness, should be used.

3. **Wall Thickness** as low as $^1/_4$ in. may be poured in the steel foundry. In special cases wall sections of $^1/_8$ in. and $^3/_{16}$ in. are possible, depending on design of the casting. The best practice is to use a wall thickness that can be poured without danger of misruns and give the necessary strength or weight. In general, sectional thickness should be proportional to the area or diameters to be run.

4. **Fillets** should be used on all inside corners where walls intersect. Unfilleted corners are weak.

5. **Avoidance of Sharp Corners.**—Fillets also obviate sharp corners in the mold, from which sand may be washed by molten steel. Size of fillets depends on shape and thickness of wall section and size of casting.

## Heat Treatment of Steel Castings

The following is abstracted from a paper by A. W. Lorenz, *Proc.* A.S.T.M., vol. xxxii, Pt. 2, p. 253, 1932:

**FULL ANNEALING** comprises heating iron-base alloys above the critical temperature range, holding above that range for a proper period, and slowly cooling through the range. Annealing temperature is usually about 100° F. above the upper limit of the critical temperature range; the time of holding is usually at least 1 hr. for each 1 in. of the heaviest section being treated. The treated castings ordinarily cool slowly in the furnace. They may, however, be removed and cooled in a medium which will prolong the cooling time as compared to unrestricted cooling in air. This treatment removes strains, improves machinability and ductility. In some cases it may be the only practical treatment, due to size of casting, maintenance of dimensions, or other limitations.

**NORMALIZING** is the heating of iron-base alloys to approximately 100° F. above the critical temperature range followed by cooling to below that range in still air at room temperature. Hypereutectoid steels rarely are normalized because of the coarsening of grain and the tendency to crystallize cementite at grain boundaries or in needles. However, it sometimes is necessary to normalize these steels by heating them above the $Ac_{cm}$ line of the Fe-C diagram. This raises yield point and tensile strength as compared with full annealing, particularly on alloy steels. In high-carbon and alloy castings, strains and brittleness usually will be induced, unless a tempering or drawing treatment follows. Castings both normalized and tempered have better ductility, higher yield point and tensile strength, and considerably better impact and fatigue resistance than full-annealed castings.

**TEMPERING** (also termed Drawing) is reheating iron-base alloys, after hardening, to some temperature below the critical temperature range, followed by any desired rate of cooling. Although tempering and drawing are practically synonymous as used commercially, tempering is preferred. This, *i.e.*, hardening and then reheating, is an illogical and confusing practice in the present (1937) state of heat treating and should be discouraged. Tempering increases ductility, removes strains, softens the metal, and improves machinability. It properly is applied only after one of the before-mentioned treatments. Used after liquid quenching, it is a means of adjusting hardness and other working properties within a wide range to suit individual requirements.

**LIQUID QUENCHING** confers maximum strength and hardness. It almost always should be followed by tempering to remove quenching strains and brittleness, and to obtain suitable modification of properties. When followed by such a treatment, most carbon and alloy-steel castings will develop the maximum combination of strength and ductility.

A.S.T.M. recommended practice for heat treatment of carbon steel castings covers full annealing and normalizing temperatures as follows: C up to 0.40% inclusive, 1650° F.; C over 0.40 to 0.60% inclusive, 1560° F.; C over 0.60%, 1525° F.

A.S.T.M. standard recommended practices recognize two types of cooling, *viz.*, furnace cooling or full annealing, and air cooling and normalizing. The higher properties obtainable by air cooling are so marked that in the field of small and medium-size castings the practice is widely followed. With large castings, the rate of cooling is not always a matter of choice. The tendency toward rapid cooling favors the use of liquid quenching. The time of holding at heat is variously recommended from $^1/_2$ to 1 hr. or more per 1 in. of cross-section. In some cases the time for large castings may exceed 2 hr. per 1 in. of section.

The liquid quenching medium may be either oil or water, water being used more generally. Temperature of quenching medium is held above 100° F. If the casting has had no previous treatment it is usual to quench from approximately ordinary normalizing temperatures or slightly lower, say 1550°-1650° F. After quenching, castings should be removed from the bath and transferred to the tempering furnace while still warm. The chief use of liquid quenching has been the treatment of alloy castings. Liquid quenching of alloy steel castings develops ultimate strengths and yield points at least 50% higher than those typical of the metal in the normalized condition, and without appreciable loss of ductility.

Ductility of cast-steel may be improved by tempering and spheroidizing treatments ranging from 750° to 1400° F. Tempering practically always is necessary after liquid quenching, after normalizing and sometimes even after full annealing. Reheating within or slightly below the critical range is common with alloy steels and is increasing in the treatment of plain carbon steels.

**SPECIFICATIONS FOR CARBON STEEL CASTINGS FOR MISCELLANEOUS INDUSTRIAL USES** (Designation A27-36T).—Specifications cover ten grades of castings, of which eight grades must be physically tested. The grades not required to be physically tested are N-1 (need not be heat treated, except when the carbon content exceeds 0.30%), and N-2 (which must be annealed). Maximum chemical composition requirements are: Manganese, 1.00%; phosphorus, 0.05%; sulphur, 0.06%.

Steel used for castings shall conform to the minimum requirements as to tensile properties for the eight grades as indicated in Table 17.

**SPECIFICATIONS FOR ALLOY STEEL CASTINGS FOR STRUCTURAL PURPOSES** (A.S.T.M. Designation A148-36).—Specifications call for three classes of castings with a total of eight grades, with minimum requirements as shown in Table 18. In relation to the chemical composition of these classes of steel castings, specifications state that the prescription of definite composition types of steel to meet the various physical requirements outlined in the specifications is not to be recommended, except by mutual agreement between the purchaser and manufacturer, since there are many types of alloy cast steel which can be made to conform to the tensile requirements in any class listed in the specifications, merely by selection of heat treatment.

### Table 17.—Specifications for Carbon Steel Castings for Industrial Uses

(A.S.T.M. Designation A27–36T)

| Grade | Tensile Strength, Minimum, lb. per sq. in. | Yield Point, Minimum, lb. per sq. in. | Elongation in 2 in., Minimum, percent | Reduction of Area, Minimum, percent |
|---|---|---|---|---|
| A–1, Unannealed.............. | 60,000 | 30,000 | 22 | 30 |
| A–2, Normalized*............. | 60,000 | 30,000 | 26 | 38 |
| A–3, Full annealed............ | 60,000 | 30,000 | 24 | 35 |
| B, Normalized*............. | 70,000 | 38,000 | 24 | 36 |
| B–1, Full annealed............ | 66,000 | 33,000 | 22 | 33 |
| B–2, Full annealed............ | 70,000 | 35,000 | 20 | 30 |
| H, Normalized*............. | 80,000 | 43,000 | 17 | 25 |
| H–1, Full annealed............ | 80,000 | 40,000 | 17 | 25 |

* Any casting that may be ordered to meet the tensile requirements above listed for normalized material of Grades A–2, B, and H may, at the option of the manufacturer, be given a full annealing treatment instead of a normalizing treatment, provided that the above listed tensile requirements for normalized material are met.

### Table 18.—Specifications for Alloy Steel Castings for Structural Purposes

(A.S.T.M. Designation A146–36)

| | Tensile Strength, lb. per sq. in. | Yield Point, lb. per sq. in. | Elongation in 2 in., percent | Reduction of Area, percent |
|---|---|---|---|---|
| Class A: | | | | |
| Grade 1..................... | 75,000 | 40,000 | 24 | 35 |
| Grade 2..................... | 85,000 | 53,000 | 22 | 35 |
| Class B: | | | | |
| Grade 1..................... | 85,000 | 55,000 | 22 | 40 |
| Grade 2..................... | 90,000 | 60,000 | 22 | 45 |
| Grade 3..................... | 100,000 | 65,000 | 18 | 30 |
| Class C: | | | | |
| Grade 1..................... | 90,000 | 65,000 | 20 | 45 |
| Grade 2..................... | 120,000 | 100,000 | 14 | 35 |
| Grade 3..................... | 150,000 | 125,000 | 10 | 25 |

### Table 19.—Specifications for Alloy Steel Castings for Valves, Flanges, and Fittings for Service at Temperatures from 750° to 1100° F.

(A.S.T.M. A157–36)

| Class....... | Ferritic Steels | | | | | | Austenitic Steels | |

| Mo, %..... | 0.40 min. | 0.20 min. | 0.30–0.60 | 0.40–0.65‡ | 0.50 max. | 0.20–0.40† | As agreed | ....... |
| W, %...... | ....... | ....... | ....... | 0.80–1.25‡ | ....... | 0.40–0.80† | ....... | ....... |

* For the more severe general corrosive conditions, and when so specified, the carbon content shall not exceed 0.07%. The addition of such elements as molybdenum, tungsten, titanium, columbium, and vanadium for purposes of stabilization shall be a matter of agreement between manufacturer and purchaser. When the purchaser requires free-machining, or better non-seizing, non-galling properties, the composition may contain suitable combinations of selenium and phosphorus or molybdenum and sulphur as follows:

| | | | |
|---|---|---|---|
| Selenium and phosphorus | Selenium, 0.20–0.35%<br>Phosphorus, max., 0.17%; | Molybdenum and sulphur | Molybdenum, 0.40–0.80%<br>Sulphur, 0.20–0.40%. |

† Either molybdenum or tungsten may be used, if desired.

‡ Either molybdenum or tungsten shall be used.

**STANDARD SPECIFICATIONS FOR ALLOY STEEL CASTINGS FOR VALVES, FLANGES AND FITTINGS FOR SERVICE AT TEMPERATURES FROM 750° to 1100° F.** (A.S.T.M. Designation A157–36) covers eight grades of materials, including six ferritic steels and two austenitic steels designated C1, C2, etc., which are classified in accordance with their chemical and physical properties and high temperature characteristics. Steels C1, C2, C4, C5 and C11 shall be made by open-hearth, crucible or electric furnace process. Steels C6, C9 and C10 shall be made by the electric furnace or crucible process.

**Table 20.—Specifications for Alloy Steel Castings**
(A.S.T.M. Designation A157–36)

| Grade | Tensile Strength, lb. per sq. in. | Yield Point, lb. per sq. in. | Elongation in 2 in., percent | Reduction of Area, percent | Grade | Tensile Strength, lb. per sq. in. | Yield Point, lb. per sq. in. | Elongation in 2 in., percent | Reduction of Area, percent |
|---|---|---|---|---|---|---|---|---|---|
| C1 | 80,000 | 50,000 | 22 | 45 | C6 | 85,000 | 55,000 | 20 | 40 |
| C2 | 90,000 | 60,000 | 22 | 45 | C11 | 100,000 | 65,000 | 18 | 30 |
| C4 | 100,000 | 65,000 | 18 | 30 | C9 | 70,000 | 30,000 | 35 | 40 |
| C5 | 100,000 | 65,000 | 18 | 30 | C10 | 65,000 | 30,000 | 30 | 35 |

All castings shall receive heat treatment suitable to their design and chemical composition. Heat treatment shall be performed before machining, except in instances when reheat treating is necessary. Unless method of heat treatment is specified by the purchaser, thus becoming a matter of agreement with the manufacturer, the type of heat treatment shall be at the option of the manufacturer.

The ferritic steels, C1, C2, C4, C5, C6 and C11 may be fully annealed, or fully annealed and drawn, or normalized and drawn, or annealed and normalized and drawn, or normalized and annealed. The austenitic steels C9 and C10 shall receive a stabilizing treatment.

Each alloy shall conform to the chemical requirements, given in Table 19, or to other chemical requirements as specified in the purchase order. The castings shall conform to the minimum requirements as to tensile properties as shown in Table 20.

**STANDARD SPECIFICATIONS FOR AUSTENITIC-MANGANESE STEEL CASTINGS** (A.S.T.M. A128–33).—**Chemical Requirements,** C, 1.00 to 1.40%; Mn not under 10.00%; P not over 0.10%; S not over 0.05%.

**Bend Test,** only when specified in the order; specimen, 12 × 3/4 × 1/2-in., to bend cold without breaking around pin 1 in. diam., to angle of 150 deg.

**Tension Test,** not required.

## 6. PERMANENT MOLD CASTINGS

Permanent mold castings are produced in molds which are used repeatedly. The term "permanent" is a misnomer, inasmuch as no molds can be used indefinitely. The types of permanent mold castings operations may be divided into gravity type, pressure die-cast and centrifugally cast.

**GRAVITY TYPE.**—Gravity-type castings are made in molds or dies constructed of various alloys of iron or steel. A machine known as the Holly permanent mold machine employs a multiple series of identical molds placed on a turntable which moves in a circular, path about a center, progressing slowly or intermittently. The open mold is coated with carbon in a sooty deposit from a torch, moves forward and is automatically closed. Metal is poured into the mold as it passes the pouring station. The casting is ejected or pulled from the mold which remains open as it approaches the point of beginning. This type of casting machine is used to make small parts for automotive service, fittings and a variety of work ranging from a few ounces to about 10 lb. It requires high-production long-run work to achieve economy. Gravity-type permanent mold castings are produced in gray iron and aluminum. Some experimental work has been done on other non-ferrous metals.

**DIE-CASTINGS** of the pressure type are obtained by forcing liquid metal into a die or mold and maintaining pressure until the casting is solid. This type of work is confined to comparatively low melting point, non-ferrous metals such as the tin, lead or zinc white metal alloys and aluminum. The most common type of pressure die-casting work is that employed in producing either linotype or monotype lines or characters in printing plants.

In the foundry industry the most common type of die casting is produced from zinc base alloys. Die-casting machines consist essentially of three parts: The melting pot where metal is melted, usually by gas flame; the die with appropriate gate channels; and the pressure equipment for forcing metal through the gate and into the mold. Hydraulic or air-operated cylinders, with mechanical toggle equipment, supply the necessary pressure. Cores may be used and many types of dies are self-coring.

Dies are constructed of special steel, and while some non-ferrous metals produce corrosive or growth destruction, machines are in operation which show an exceedingly long die life. High production is possible with automatic machines and castings weighing from a few ounces to 15 pounds are produced. On heavier castings, it is necessary to cool the dies by water-jacket or some equally effective device.

Aluminum die-castings, notably aluminum pistons and radiator grills, are produced in large quantities. Inherent soundness and uniformity are claimed for aluminum castings made by this process. For data on die-casting alloys see pp. 4–60 to 4–62.

**CENTRIFUGAL CASTINGS.**—The earliest application of spinning molds to obtain round or cylindrical castings by the application of centrifugal force was in the cast-iron pipe industry. A major portion of gray iron pipe produced in the U. S. today is made either in permanent molds or in hollow molds lined with a thin layer of sand. The processes differ only in the mold characteristic. The de Lavaud process of producing centrifugal pipe involves the use of a thin, forged steel mold mounted horizontally in a water-cooled housing. The bell of pressure pipe is formed by a single sand core fitting in the end of the permanent mold.

In operation, a predetermined quantity of molten iron at high temperature is poured into a ladle at the spigot end of the machine, connected by a long channel or trough running to the bell end of the pipe. The mold is rotated at slow speed as the metal is spilled into the mold along its entire length. The speed of rotation then is increased and centrifugal force drives the metal outward so that it coats the entire inner surface of the mold. Rotation is maintained until initial cooling or solidification is accomplished. The pipe then is drawn from the mold by gripping the bell end and removing the pipe longitudinally from the fixed gripper. The pipe is annealed, coated and lined. Pipes are made varying in length up to 30 ft. and in diameters from 3 to 30 in.

In the sand spun process the steps are similar, with the exception that the mold is lined with a layer of sand rammed about a central pattern. This sand is surface dried before the mold is placed in the casting machine.

Experimental work has been performed on automotive fly-wheels cast flat in a machine which rotates the mold in a horizontal plane. Another application of centrifugal molding is in the production of automobile brake drums. These machines employ a vertically-operated rotating mold which forms the drum against which the brake bands are applied in operation. This outer drum, in many cases, employs steel fittings which are cast in place as the mold is poured.

## 7. MOLDING SAND

Molding sand consists of quartz, feldspar and clay in varying quantities, depending on the location from which it is obtained. The qualities demanded of a good molding sand are: refractoriness, or ability to resist the heat of molten metal; strength, or ability to withstand the pressure of molten metal without distortion; permeability, permitting ready escape of gases from the mold. Refractoriness is furnished by the quartz, or silica, of the sand, which if pure is practically infusible. Strength is due to the clay which acts as a bond between the grains of quartz. Permeability depends on grain structure and on quantity of clay. The more regular the silica grains and the smaller the quantity of clay substance present, the greater the permeability. A coarse sand is more permeable than a fine one, and a sand with round grains more permeable than with angular grains. Other desirable qualities are the ease of destruction of the mold after pouring and a low percentage of "burned" sand resulting from contact with molten metal. These two latter qualities are promoted by the clay bond being highly refractory. Moldenke defines the ideal molding sand as one consisting of uniform-sized, rounded grains of silica, each grain coated with the thinnest necessary layer of the most refractory and fattest clay to be had. O. E. J. Abrahamson (*The Fdry.*, March–Sept., 1930) says that the production of smooth castings depends mainly on the amount of fine grains (passing 300 mesh or finer) in the sand, the nature and amount of bond, the moisture content, and the method of preparation of the sand for use. The number of coarse grains (those remaining on a 100-mesh sieve) is relatively unimportant.

The variable factors in sand influence castings production more often than do metallurgical or mechanical considerations. The selection, blending and use of sand formerly was largely a matter of personal judgment, but mechanical and chemical methods of testing sand have largely come into use, particularly in production foundries, for both molds and cores. A joint committee of technical societies, sponsored by the Am. Foundrymen's Assoc. has investigated and standardized these methods, which are given in detail in Testing and Grading Foundry Sand, *Trans.* A. F. A., 1931.

In continuous production foundries, sand may be used as often as 4 or 5 times an hour, as compared with its use once a day, the usual practice up to about 1920. This continuous use requires cooling, tempering, replenishment of bond, and the addition of other variables to those inherent in the sand. The absolute uniformity required has developed sampling, blending, testing of the natural sand, and a new technique in treatment. Synthetic molding sand, *i.e.*, sand made of washed silica with the admixture of various types of clay bond has been successful in production foundries. Natural sands, continuously used, require the addition of bond to replace that destroyed by mold heat. Correct moisture content

influences maximum strength characteristics; permeability, as affected by even slight changes in moisture content, may be controlled by rapid and effective routine tests.

**COMPOSITION OF MOLDING SAND.**—Molding sands occur in many parts of the United States and vary in the above qualities and in analysis over a wide range. Moldenke gives the following comparison of the ideal American sand and the average of 76 sands from various localities reported in *Trans.* A. F. A., xxi, p. 85, 1913.

| | Quartz | Clay | Feldspar |
|---|---|---|---|
| Ideal.................... | 84.00 | 13.50 | 2.50 |
| Average.................. | 65.53 | 21.75 | 12.75 |

The size of casting and the metal must be considered in the selection of molding sands, according to C. P. Karr (*Trans.* A. F. A., xxiv, p. 155, 1915). For steel castings, the sand should contain 97% or more silica with a small amount of clay for bonding purposes. Sands for iron castings should be loamy with a texture varied with the size of the casting. Sands for bronze should be of fine grain, good bonding power and have a high permeability. Sands for brass and aluminum should be even grained, loamy and should also have high permeability.

Table 21 shows the percent of fineness of the molding sands tested by Moldenke. The finest sand possible that will afford adequate venting power, should be used in any given mold, due consideration being given to the size of the mold. The finer the sand the better will be the surface of the casting.

Table 22 shows the maximum, minimum and average quantities of quartz, clay substance and feldspar in the 76 sands.

**STRENGTH OF MOLDING SAND.**—Table 23 shows the results obtained in strength tests of the 76 sands tested by Moldenke. Crushing strength of sand is important, as on it depends the resistance of the mold to pressure of the molten iron. The strength of

* Minutes required to drive 1 gal. of air, in a 1/4-in. pipe through a cake of dried sand 1 in. thick under a pressure corresponding to a 7-in. head of molten metal, in excess of time required to pass out of apparatus freely.

† Weight, lb., required to rupture bars 1 in. sq. placed on supports 4 in. apart.

‡ Weight, lb., required to crush columns of sand 1 in. sq. and 2 in. high.

molding sand depends largely on its clay content. The larger the quantity and fatter the clay, the stronger will be the sand. High strength, however, usually means low permeability, since the clay fills the voids between the sand grains. Strength of molding sand is tested by slowly pushing bars of sand 1 in. square and 1 ft. long, over the edge of a glass plate and noting the length of the overhang as they break.

Another method is to break a 1 in. square bar supported on knife edges 4 in. apart by a load applied at the center. The strength of the sand is affected by the amount of water used for tempering, but tests usually are made with 5%, 7 1/2% and 10% of water.

## Sand Testing

Complete details of sand testing methods available in testing and grading foundry sands are given in Testing and Grading of Foundry Sand published by Am. Foundrymen's Assoc., 1931. A brief of the essential tests follows:

SAMPLING.—For plant control tests, an average representative selection of facing or heap sand should be made as tempered for use in mold or core. To determine properties under suitable foundry conditions, several water contents should be tested to develop that giving the maximum degree of property being investigated, starting with a water content that leaves the sand dry, and increasing by small increments. Open sand, bonded with colloidal clay, may require increments of 0.1%, while natural bonded sands may be tested satisfactorily with increments of 2%. In tempering, care should be taken to distribute water evenly through the sand, with no dry lumps remaining. The sand should temper in a closed receptacle for several hours before testing.

**THE MOISTURE CONTENT** of sand sample is determined as follows: Dry 100 gm. of tempered sand for 1 hr. at 105 to 110° C. (221–230° F.). Cool in a desiccator or covered dish. Reweigh. Loss of weight in grams is percentage moisture content.

**PERMEABILITY** is that physical property of sand that permits passage of gases, and on which depends the venting qualities of molds and cores. A high permeability sand has good venting quality due to its "openness." The natural characteristics of the sand and binders, the density to which they are packed, and the percentage of moisture used for tempering, are important in regulating permeability. Permeability is determined by the rate of flow of air at a given pressure through a standard specimen of sand. In the standard test a 2-in. (5.08 cm.) column of sand (area, 3.1416 sq. in. or 20.268 sq. cm.), rammed under uniform and predetermined conditions is placed in a cylinder equipped with a manometer. The time required to force 2000 cu. cm. of air through the sand is determined. Permeability, $P = (q \times h)/(a \times h \times t)$, where $q$ = cu. cm. of air forced through specimen; $h$ = height of specimen, cm.; $p$ = air pressure, grams per sq. cm.; $a$ = area of specimen, sq. cm.; $t$ = time, min. A number of variations in standard test procedure are optional for rapid shop control, green sand permeability and mold surface permeability requirements.

**THE STANDARD STRENGTH TEST METHOD** has been approved as standard to be used where comparisons are necessary. Compressive, tensile, shear or bar strength tests all may be applied as routine in foundry practice control, depending on properties which sand is intended to develop in use, but compression test is standard in case of disagreement. The compressions test may be made on the green and permeability specimen (see above) by applying a load uniformly to the two plane surfaces at the rate of 30 lb. per min. with a tolerance of 10 lb. per min.; the load to be applied along the axis of the cylindrical specimen. Compressive strength is the average of three tests, lb. per sq. in. of cross-sectional area. Various types of apparatus are provided for standard compression tests.

**FINENESS TEST** refers to the size distribution of the grains. The fineness of sand affects permeability, strength, moisture required for mixing and affects the surface of the casting. In fineness tests, U. S. Bureau of Standards sieves Nos. 6, 12, 20, 30, 40, 50, 70, 100, 140, 200, and 270 are used. These sieves, 8 in. diam., are known as half height. A pan at the bottom of the set collects material passing the lower, 270-mesh sieve. In testing, 50 gm. of dry sand are weighed into the uppermost of the series of sieves, previously placed in a shaker. The sieves are shaken for a definite time, depending on type of shaker. The amount of sand remaining on each sieve is weighed and expressed in percentage of the original sample weight. The portion passing the 270 sieve is called pan material. Sand containing clay or bonding substance is washed according to a predetermined procedure, the bonding material siphoned and the remaining sand dried and tested as above.

**MOLD SURFACE HARDNESS.**—The density to which molding sands are rammed affects two important physical properties of the mold: 1. Ability of the mold surface to withstand pressure of molten metals, 2. Relative permeability of the mold. An indication of these properties is obtained by a device to determine hardness of mold surface, which measures depth of penetration into the mold surface of a round-nose plunger 0.2 in. diam; the load is applied in a direction perpendicular to the mold surface. The instrument has a recording device that indicates to 0.001 in. the penetration of the plunger. For calibration, a pressure of 237 gm. on free end of plunger should indicate a movement of 0.1 in. on the dial. The instrument should be checked at frequent intervals.

**DYE ADSORPTION TEST** of molding sand is solely to ascertain the nature of the clay substance present. Different sands possess widely different adsorption capacities. The colloids in molding sands are mostly inorganic, comprising hydrated aluminum silicate, hydrated iron oxide, hydrated silica acid and other hydrated minerals. All of these are gelatinous and sticky and give the sand the property of bond. Strongly bonded molding sands commonly possess clay substance high in colloid content as measured by dye adsorption test. Weaker bond sands usually show a lower dye adsorption corresponding to the smaller quantity of colloids in the clay substance of those sands. Methods of making the dye adsorption test are given in the above-noted booklet.

**CORES AND CORE MIXTURES.**—Cores are made of sand and a suitable binder, which may be either dry or liquid. The sand should be high in silica to resist heat of the molten metal, and low in alumina. Old sand and gangway sand may be used in part for the sand mixture. The grains should be well rounded to afford venting power to the core. Linseed oil makes the best binder, but is expensive. Other binders in common use are flour, glue, molasses, resin and resin oil, as well as many proprietary compounds.

The usual proportions of the foregoing materials are as follows:

**Linseed Oil,** 1 part oil to 30 parts sand. Cores are strong, porous and easily removed from the casting.

**Flour,** 1 part flour to 18 to 30 parts sand. The lower the proportion of flour, the more porous but weaker will be the core. The flour should be made into a thin boiled paste which is used to dampen the sand.

**Glue,** 2 lb. of glue dissolved in 3 gal. of water to 100 lb. of sand. Cores are smooth, but friable. They give off less gas than other cores.

**Molasses,** 1 part, mixed with 20 parts of water, usually is used as a spray for core surfaces.

**Resin,** 1 part to 20 or 30 parts of sand.

**Resin Oil,** 1 part to 18 to 24 parts of sand.

Cores containing molasses, flour or glue must be kept dry as they soften when exposed to dampness. They should not be placed in the molds very long before pouring.

The results of a series of experiments made by A. M. Loudon are given in *Trans. A. F. A.*, xv, p. 34, 1906. The following core mixtures which gave satisfactory results, have been selected from those published.

1. Old flour sand, 1 part; new molding sand, 1 part; sharp or beach sand, 1 part; 1 part Syracuse dry core compound with 35 parts sand. Cores dry quickly; are clean and sharp and resist dampness and leave a good surface.

2. Old flour sand, 2 parts; new molding sand, 1 part; beach or sharp sand, 1 part; 1 part dextrine or British gum mixture to 150 parts of sand, tempered with water. Cores are strong, dry easily and have sharp edges. Useful for large cores.

3. Old sand, 1 part; new molding sand, 1 part; sharp sand, 1 part: 1 part dextrine to 100 parts of sand. Useful for small intricate cores.

4. Old sand, 1 part; new molding sand, 1 part; sharp sand, 1 part; 1 part Wago core compound to 30 parts of sand. This mixture makes a good core which gives off but little smoke.

5. New molding sand, 1 part; sharp sand, 1 part; 1 part Wago core compound to 35 parts of sand. Makes a strong, true and sharp core, but is not so easily removed from castings as No. 4. Resists dampness well.

6. Old sand, 1 part; sharp sand, 1 part; new molding sand, 1 part; 1 part Cleveland core compound to 30 parts of sand, tempered with water. Makes strong core for general use. Easily removed from the casting.

7. Old sand, 1 part; sharp sand, 1 part; new molding sand, 1 part; 1 part flour to 18 parts of sand. Makes a good core for general work.

8. Sharp sand, 30 parts; Holland linseed core mixture, 1 part. Makes a strong core for small and medium shapes. Requires venting. Resists moisture.

9. Sharp sand, 35 parts; Syracuse core oil mixture, 1 part, tempered with water. Makes good cores but requires venting. Resists dampness well.

10. New molding sand, 1 part; sharp sand, 1 part; old sand, 2 parts; 1 lb. of glue to 100 lb. of sand. Recommended for small cores. Used without venting.

11. Sharp sand, 1 part; new molding sand, 1 part; old sand, 1 part; 1 lb. glucose to 100 lb. sand. Makes a first-class core, easily removed from the casting and emitting no smoke.

An exhaustive research on core sands, core binders and core-room equipment was made by H. M. Lane (*Trans.* A.S.M.E., xxxiii, p. 735, 1911). Mr. Lane says that a core of the most exacting requirements, made of oil-sand mixtures, must have a tensile strength of at least 75 lb. per sq. in. The sand must contain no loam which will destroy the bonding value of the oil. The paint and varnish oils, including China wood, Soya bean, corn and cottonseed oils, are used in core oils. Blended oils also carry resin and neutral oil. The latter does not add appreciably to the binding power of the compound but carries the resin into the mixture and gives a waterproof oil of sufficient strength for ordinary work at lower cost than linseed oil. Greater strength may be afforded by using a bonded sand; *i.e.*, a sand containing clay, or by using flour, dextrine or other glutinous material. Strength of the dry core is governed by the amount of pressure it must resist as metal enters the mold. All cores tend to float, and if not rigid enough, may be broken or displaced.

**Facing Materials.**—Facing materials are those substances added to the molding sand rammed next to the pattern to give a smooth finish to the casting. Formerly it was the custom to add a finely ground gas coal to the sand, about an inch of this mixture being rammed against the pattern, the balance of the mold being formed of ordinary molding sand. Moldenke claims that the advantages of this so-called " sea coal " are much overrated and advocates the use of prepared facings, such as graphite, ground coke, charcoal or anthracite, soapstone, etc. Graphite, prepared with a binder to cause it to adhere to mold surfaces is widely used on green sand molds, being dusted on and smoothed with the trowel. On dry sand molds it should be wet with molasses water, clay wash or other substances of adhesive properties, and brushed on.

## 8. MOLDING MACHINES

Molding machines may be used either to save time in the ramming of the mold or in drawing the pattern. The latter saving is due not only to the more rapid work of the machine as compared to hand draft but also to the elimination of the labor of patching, which is frequently necessary with hand drawing. The density of the machine-rammed mold is more uniform than the hand-rammed one and the castings usually are free from scabs, blisters, etc.

**TYPES OF MOLDING MACHINE.**—Molding machines may be classified according to the method of ramming, as hand-rammed, squeezer, jar-ram machines or gravity machines.

**The Squeezer,** as the name implies, packs the sand by squeezing it between two platens. It is adapted to the average type of mold where the depth of sand is not excessive and where there are no deep pockets involving large bodies of hanging sand. The squeezing operation can be performed either by hand or power, compressed air usually being the medium for the latter.

**The Jar-ramming Machine** comprises a table upon which rest the pattern, flask and its contained sand. The table is lifted a short distance and allowed to drop suddenly, the inertia of the falling sand packing it around the pattern when it is brought to rest by striking the table. The lift of the table ranges from $^1/_4$ to 3 in., 2 $^1/_4$ in. being perhaps the average lift. With this machine the mold is densest immediately around the pattern and least dense at the outer surface. The number of blows to obtain the necessary hardness or density of the molding sand varies with: 1. Nature of the molding sand. 2. Kind of metal, brass, cast iron or steel. 3. Depth of flask. 4. Locally, *i.e.*, with the individual ideas of the foundrymen. The range is from 3 to 100 blows, at about 80 blows or jars per minute. Tests to determine the number of effective blows to give the greatest density of the molding sand showed that at 80 blows the sand had almost maximum density, a larger number of blows increasing the density but little, while the sand cracked in places.

Jar-ramming machines often are combined with the squeezer principle, the mold being jarred a few times to pack the sand in cavities and around corners and edges of the pattern and flask. The operation is finished by squeezing the mold as in the plain squeezer machine.

**The Shockless Jarring Machine,** built by Tabor Mfg. Co., Philadelphia, and described by Wilfred Lewis (*Trans.* A.S.M.E., xxxii, p. 789, 1910), has a table mounted on a plunger fitted into a cylinder base forming an anvil, and supported on springs which are compressed when the table is lifted by compressed air. When the air is released, the table drops and the springs force the anvil upward, each having approximately equal momentum at the instant of impact. The sand is rammed without any of the shock of impact being transmitted to the foundation or surrounding floor.

Molding machines also can be classified as: Split pattern machines, for molding patterns which can be divided on a plane and mounted on a plate; stripping-plate machines in which the pattern is drawn through a plate which supports the sand in the mold while the pattern is drawn; roll-over machines, in which the completed mold is rolled over by the machine and the pattern drawn in the rolled over position. Either hand or power may be used for any or all of the operations of these machines. The several fundamental types of machines are combined to form a great variety of machines to suit various foundry conditions. The following classification is given by J. J. Wilson and A. O. Backert (*Trans.* Am. Fdry. Assoc., xxiv, p. 269, 1916):

| | |
|---|---|
| Squeezers. | Hand squeezers. |
| | Power squeezers. |
| | Hand squeezer with stripping plate attachment. |
| | Squeezer of the adjustable drop plate type. |
| | Split pattern squeezers, hand and power type. |
| | Automatic machines. |
| Stripping Plate | Stripping plate machines, hand and power draw. |
| | Stripping plate machines, drop plate type. |
| Roll-over | Hand-rammed roll-over. |
| | Hand-rammed, power roll-over and power draw. |
| | Hand-rammed, hand roll-over, foot draw. |
| | Gravity machine, roll-over, pattern draw type. |
| Jar-ramming | Plain jar-ramming, air and electrically operated. |
| | Foot jolt machine with roll-over attachment. |
| Combination Machines Embodying Jar-ramming Principle. | Jar-ram, roll-over, pattern-drawing. |
| | Jar-ram and squeezer. |
| | Jar-ram, squeezer and pattern-drawing. |
| | Jar-ram, squeezer, roll-over, pattern-drawing. |
| | Jar-ram, pattern-drawing. |
| | Jar-ram, roll-over. |
| | Jar-ram, air-squeezer, stripping plate. |
| | Jar-ram, split pattern. |
| | Jar-ram, squeezer, split pattern. |
| | Jar-ramming and stripping plate. |

**SANDSLINGERS.**—A molding method differing from the conventional types which employ pressure squeeze or jolt ramming is defined as sand slinging. It involves throwing sand into the mold, relying on an inertia effect to compact the sand about the pattern. It is an outgrowth of the old-time molder's practice of throwing handfuls of sand against a pattern prior to adding additional sand which is hand rammed or jolted.

The mechanical ramming of sand by the sandslinger method is accomplished by feeding the sand into the path of a revolving cup which projects the sand outward against a fixed liner forming a wad. After the wad is formed, it is projected from the slinger head at a velocity of 4000 to 8000 ft. per min., which is ample to ram molds to varying degrees of density, a new wad being formed and discharged at each revolution of the ramming motor.

Mechanically, it is made so it can be passed over various size molds, from snap flasks to pit molding, producing castings that weigh ounces or many tons. In ramming molds, it can be passed over the mold by man or mechanical power. In production work of various kinds, it requires no operator. Sandslingers range in their capacity from five to thirty cubic feet of sand per minute, and they operate entirely by electric power.

**CORE BLOWING MACHINES.**—The pneumatic core blowing machine is used for producing small and medium size dry sand cores in commercial quantities, ranging in size from small cores such as are used for small fittings and lock work, up to cores weighing approximately 50 lb., such as automobile crank-case cores and similar work of a "chunky" type. Lighter cores of the rangy, lacy type such as automobile jacket work, are being blown successfully up to approximately 35 in. long.

The core blowing machine consists principally of a sand reservoir and blow plate mounted on a carriage which travels back and forth from the filling to the blowing positions. This carriage is suspended from the upper structure of the machine, which is in turn supported on a base carrying the table and vertical and horizontal clamping mechanisms. The core box is filled by projecting air at high pressure (approximately 110 to 120 lb. per sq. in.) onto the sand in the reservoir, thus forcing a stream of sand and air at high velocity through the holes in the blow plate into the cavity of the core box. Vents are provided in the core box to allow the air to pass on through. The vents resist the passage of the sand grains, and trap the sand in the core box cavity. The size and location of the vents are so arranged that the core box will fill properly.

The satisfactory operation of a core blowing machine requires first-class metal core boxes, with tight joints throughout, and sufficient land at the parting line and around the blow holes to insure a tight seal. Opposite outside surfaces must be machined parallel, so that the box will clamp squarely in the machine. Metal core dryers are necessary, except when the cores are of a nature that will permit standing them on a plate, following the usual practice.

The use of a core blowing machine should be confined to conditions where the expense for metal core box equipment is justified, and where the required sand mixture is free from heavy bond and sufficiently fluent to work freely in the machine.

**FIELD OF DIFFERENT TYPES OF MOLDING MACHINES.**—It is difficult to define the particular class of work to which each type of machine is best adapted. In general, the squeezer is used on comparatively shallow molds, or molds of the bench work class, while the jarring machine is adapted to deep molds, or molds where there are cavities in which it would be difficult to pack the sand by pressure alone. It may be said to be a machine for light or heavy floor work. The combination jar-ram squeezer is used for work a little deeper than that for which the plain squeezer is adapted, or where the sand requires hand tucking in pockets and corners, before the squeezing operation. Instead of hand tucking the mold is jarred a few times and then squeezed.

The split-pattern machine is used where the patterns are symmetrical or of the flat-back type. With symmetrical patterns, but one pattern plate is used, cope and drag being molded from a double set of half patterns, the mold in the right-hand side of the drag matching that in the left-hand side of the cope and *vice versa.* With flat-back work, all the drags are molded from the pattern, and then a blank plate is placed in the machine and all copes are made.

Stripping-plate machines are used where there is a long run of duplicate work. They are not economical for short runs due to the expense of fitting up the stripping plates. For short runs, where the sand would require support while drawing the pattern, a roll-over pattern-drawing type of machine is preferable. Stripping-plate machines are especially adapted to gears, sprockets and patterns of irregular outline such as binder and mower frames.

The roll-over machine is useful where the size of the mold is such that the labor of turning it over is considerable. While it may be used for light work, its true field begins with what is known as heavy bench or light floor work, and extends in the power machines to molds weighing several tons.

The roll-over machine may be either a plain hinged or a straight draft machine. In the former, the pattern plate revolves about the hinge-pin, while in the latter it is lifted vertically until the pattern is clear of the mold and is then rolled back to molding position. The former type may be used on shallow work with considerable draft, such as stove-plate, grates, etc. The straight draft machine is used for deeper work, as fly-wheels, pistons, cylinders, automobile crank- and transmission-cases, etc. In connection with jar-ramming the roll-over machine is used for railway trucks, planer and boring mill housings, milling machine columns, bases and tables, lathe beds, ship castings, etc.

For details of construction of molding machines, sizes, capacities, and the adaptability of a particular class of machine to a given type of work, manufacturers of this class of equipment should be consulted.

## 9. MISCELLANEOUS FOUNDRY EQUIPMENT

**LIFTING BEAMS** for foundry use are of various forms. For light loads, a light forged spreader, of triangular form with hook extensions at the two lower corners of the triangle for attaching the load, is serviceable. For large, heavy copes, a beam in the form of a cross is frequently used, to permit the cope to be suspended from 4 or more points. I-beams, suspended at two points from a lifting ring with the load slings placed outside the points of suspension, are the strongest and most reliable of all types. Table 24 gives safe loads for this type of beams.

**Sandblasts** for cleaning castings are of the following types: gravity, suction and pressure. Good work may be done with a nozzle 1/4 or 3/8 in. diameter, with air pressure of 25 to 75 lb. per sq. in., depending on the material to be cleaned. Steel castings take higher pressures. The quantity of air used depends on air pressure and diameter of nozzle. No more air can be used than will be passed through the nozzle regardless of the diameter of air inlet. Since quantity of air used will increase rapidly as nozzle diameter and pressure are increased, the nozzle should be inspected and replaced at intervals. Quantity of air and power consumption are shown in Table 26.

The flow of sand should be so regulated as to deliver just enough to give a quick and thorough cleaning. This is effected by allowing each abrasive grain to strike the surface without interfering with its neighbors. When the sand can be seen issuing from the nozzle, the feed is about right. The nozzle should be held about 6 in. from the work and at an angle of 30° to 45°.

**AIRLESS ABRASIVE CLEANING.**—A type of machine employing the centrifugal method instead of pneumatic pressure for abrasive cleaning has been developed. This type of machine has a rotating head with cups or vanes, which takes small quantities of abrasive material, such as steel shot or grit. As each vane rotates, it delivers the abrasive material at high velocity and within a predetermined area on the surface of castings. The abrasive action of the material cleans the sand from casting surface. The same type of abrasive propelling element is employed in certain barrel or tumbling machines.

# MALLEABLE CASTINGS

By Enrique Touceda

The production of malleable castings dates from Réaumur's discovery that when a piece of hard and brittle white cast iron—that is iron, all of whose carbon is in combined form—was heated to a certain temperature and maintained at that temperature for a certain length of time, the iron then would be considerably less hard and brittle. Subsequent investigation showed that softness and ductility of the annealed product depended upon the composition of the white iron, and later researches that the most trustworthy product, measured by high ultimate strength and ductility, could be obtained only if the elements of the white iron were restricted to certain prescribed limits and the heat treatment conducted in accordance with certain rules, the violation of these rules resulting in an inferior product.

The manufacture of malleable castings thus comprises two steps: 1. The making of white iron castings of correct composition. 2. Heat treatment of the proper character. The melting is usually conducted in a reverberatory furnace (more commonly called an air-furnace). The open-hearth and electric furnaces are also used.

The customary mixture consists of: Pig iron, sprues from the previous heat and steel scrap for the purpose of carbon control. With the reverberatory or open-hearth furnace, the oxidizing action of the hearth atmosphere lowers the silicon and carbon of the charge —both during melting and also while molten metal is receiving sufficient superheat to enable the castings to be made without danger of misruns—to a point at which no carbon will be precipitated upon solidification. The castings then will show a white fracture. The product of the melting furnace, irrespective of the type used, is known as "hard iron" and should be, but not always is, completely white in fracture.

**COMPARISON OF MALLEABLE WITH GRAY IRON AND STEEL CASTINGS.**— Normal malleable cast iron as made in the U. S. is structurally unlike any other ferrous casting. The gray iron casting to which it is sometimes compared by the uninformed, usually consists of a ground-mass of varying proportions of ferrite and pearlite, through which are regularly distributed plates of graphite varying in thickness, length and curvature. If all the carbon is graphitic, which is rare, the ground-mass will consist entirely of ferrite. In limited cases where the combined carbon is high, say in the neighborhood of 0.90% or more, the ground-mass will consist of pearlite, or pearlite and free cementite. Gray iron castings sometimes are heat-treated, to facilitate machining, to increase the strength, hardness, or wear when pearlite predominates in the matrix, or to graphitize some of the pearlite in very low silicon cast irons. Hence the grain size in all sections in unannealed castings varies directly as the thickness. Since the percentage of combined carbon present in a gray iron casting depends appreciably upon the rate of cooling, the relative proportions of ferrite or cementite to the pearlite in the ground-mass will vary in the thick and thin sections of the same casting. The ordinary steel casting consists of a ground-mass of free ferrite and pearlite, the amount of pearlite increasing with the combined carbon content. So far as the structural constituents are concerned, the structure will be similar in the thick and thin sections, provided the sections are not abnormally disproportionate. The soft unannealed steel castings usually are sold in competition with malleable castings. In these the grain size will be coarse throughout the casting, and larger in the heavy sections than in the light sections.

The structure of malleable iron more closely resembles that of wrought iron, both having a ground mass of ferrite, the inert constituent in the malleable iron being temper carbon and in wrought iron, slag. The ferrite of the former, however, is much stronger because of the very large amount of silicon held in solid solution. The normal structure of malleable iron consists of but two constituents, both of which are soft. Its ground mass is practically 100% carbonless iron, or silico-ferrite, while uniformly distributed through it are small particles of carbon very different in shape and size from the plates of primary graphite that occur in gray iron. The white iron, which forms the basis of malleable castings, consists of cementite or carbide of iron, the hardest constituent that can exist in iron or steel, and cementite mechanically mixed with soft carbonless iron. Through heat treatment the carbide of iron is decomposed into its two soft constituents.

Inasmuch as malleable cast iron, due to the method of manufacture, is a product heat-treated slightly above the critical range, the grain size throughout the casting must be uniform and almost as fine as it is practical to obtain. This is of extreme importance in castings subject to dynamic stresses. Since the entire metallic part of a correctly annealed malleable casting consists of carbonless iron, such castings naturally must be soft and ductile, tough and free from internal stress.

**COMPOSITION OF MALLEABLE CASTINGS.**—The average reverberatory furnace mixture, to yield a tensile strength around 54,000 lb. per sq. in., accompanied by an elongation of 18.00% or over and the hard iron resulting therefrom, run about as follows:

| | Silicon | Max. Phosphorus | Max. Sulphur | Manganese | Carbon |
|---|---|---|---|---|---|
| Mixture........... | 1.25–1.35 | 0.20 | 0.10 | 0.60 | 2.65–2.80 |
| Hard Iron.......... | 0.95–1.10 | 0.20 | 0.10 | 0.22–0.30 | 2.00–2.40 |

Silicon in the mixture should be so adjusted that when the bath has received sufficient superheat to successfully run the castings, enough silicon has been eliminated from the bath to prevent graphitization upon solidification of the castings of heavy sections. If the silicon has not been lowered enough to accomplish this, it indicates too great an initial silicon in the mixture. This condition can be corrected by allowing the metal to remain in the furnace until both the silicon and carbon are still further lowered, which process, however, is wasteful of fuel. If the fracture of the test sprue, prior to complete superheating, shows white, the initial silicon of the mixture was too low and a white-iron composition will result that will yield, upon heat treatment, castings of abnormal steely fracture, lacking ductility. The addition of certain silicon-manganese-carbon combinations will correct this condition. Silicon can be replaced by the addition of ferro-silicon, and manganese by addition of ferro-manganese. The best practice is to use silico-spiegel which contains 6 to 12% of silicon and 17 to 22% manganese. As this alloy contains too little carbon, this element must be added separately. The usual procedure is to add a sufficient amount of petroleum coke for carbon replacement. Additions should be made immediately it is realized that any of the elements have been unduly eliminated. It is the common practice to make preliminary analyses as the heat progresses, and additions should be made immediately such analyses indicate that such are necessary.

**Phosphorus and Sulphur.**—Phosphorus in white iron should be under 0.20%; sulphur preferably under 0.10%.

**Manganese.**—The permissible amount of manganese is a function of the sulphur content as follows:

| | | | |
|---|---|---|---|
| Sulphur................ | 0.04 | 0.07 | 0.10 |
| Manganese............. | 0.20–0.24 | 0.23–0.27 | 0.27–0.34 |

**Carbon.**—If high tensile and ductile properties are desired, the carbon in the white iron should be about 2.25%. Such a carbon content will yield molten metal of sufficient fluidity to pour intricate castings. If less fluidity is permissible, the carbon can safely be as low as 2.00%.

If mixtures are made to accord with the above recommendations, hard iron of a composition suitable for sections up to 1 1/2 in. thick should be obtained without difficulty. Failure to obtain the proper primary mixture either through ignorance or lack of knowledge of the exact composition of the raw materials, may give "low-heat" or "high-heat" iron. Low-heat iron is a white iron so high in either silicon or carbon, or both, that primary graphite will be found in the heavy sections of the castings. No subsequent heat treatment can rectify this defect, and the castings will be undependable, as they will lack strength and ductility. This trouble is not likely to occur with any reasonable thickness of section if the carbon plus silicon is from 3.40 to 3.30%. High-heat iron, irrespective of the type of furnace producing it, is an iron so highly oxidized that too much silicon, carbon and manganese have been eliminated, or iron from a mixture in which the initial silicon was so low that white iron will have a composition giving an abnormal fracture when annealed, while it will be unsound and the surface covered with pin point holes.

**HEAT TREATMENT.**—The heat treatment of white iron castings, commonly, although improperly, called annealing, has for its object the decomposition of the free and pearlitic cementite that constitutes a large part of the structure of the white iron, by means of temperature, time and slow cooling. The very hard constituent, "cementite," was formed through a chemical union of iron and carbon, both of which are soft. The decomposition of the cementite brings about their separation. Consequently, the resultant product is a soft, strong, ductile and very easily machined metal, as no hard or brittle constituent is present. The author has frequently pointed out that the "anneal" in the case of hard iron castings should more properly be called a heat conversion rather than an annealing process.

In annealing, the castings are packed in rectangular or circular pots without bottom or cover, called rings. Rectangular rings usually are 24 × 18 × 15 in. high, and circular rings about 24 in. diameter by 15 in. high, the thickness of metal being 1 in. One of these rings is placed upon an iron "stool" of such horizontal dimensions that its edges extend about 3 in. beyond the sides of the ring. The stool serves both as a bottom for the ring that is placed upon it, and as a base for the entire assemblage of rings that are to be superimposed upon the lowest one. The stool is some 6 in. high and designed with feet so spaced that the forked lifter of the charging truck can slide under it to slightly raise the load and permit the truck to place it in the annealing oven. The detailed procedure is so to fill the ring that rests directly on the stool with castings and packing that each casting will be completely surrounded with the packing material. As soon as this ring has been packed solid, other rings in turn are superimposed upon it and a similar procedure followed in the case of each ring. The entire set, which may consist of 4 or 5 rings, is called a stand. The castings in the top ring should be kept not less than 4 in. from the top and packing to that depth filled in over them. A 2-in. luting of mixed clay is placed over the top of the stand, the joints between the rings being luted with the same material. After transference to an annealing oven, which is sealed, the castings are subjected to the following heat cycle: 1. Temperature of the oven is gradually raised to 1550° F. or higher in 40 hours. 2. The temperature is held at 1600° for about 60 hours and firing then discontinued. 3. The temperature is lowered at a rate that should not exceed 10° per hour, until it is certain that the temperature of the castings does not exceed 1200° F., after which the rate of cooling can be progressively accelerated. Heat treatment thus covers a period of 6 1/2 days. It is not recommended, nor is it practical in an ordinary type of oven, to attempt to shorten this period.

The tunnel type of oven is about 200 ft. long. This is constantly under fire and the annealing process is continuous, since the stands are introduced at one end of the oven on cars and withdrawn at the other end, the rate of travel through the oven being adjusted to accommodate the cycle adopted. By this method the total period of annealing can be shortened to not greatly exceed 100 hr. with a consequent saving of fuel.

A type of oven in which the anneal can be run through in a much shorter time is the car-type electric annealing oven, in which an anneal can be completed in three days or less. This method of annealing is advantageous because it makes possible more prompt delivery, and because the surface decarburization of the castings can be more closely controlled.

Another type of annealing apparatus is the muffle oven, in which castings that can be annealed without undue warping are stacked very closely together on the floor of the oven; other layers of castings are superimposed until the oven has been completely loaded. Frequently, plates of thin sheet steel are placed between each of several layers if the castings are not too large. As the products of combustion do not come in contact with the castings, a packing material is unnecessary, since if the muffles are tight no danger will exist of the castings being scaled. On the one hand, a product of the highest character can be produced in such an oven. This type is very flexible, due to the fact that very large castings cannot be heat-treated in any other type of annealing oven.

Small car-type annealing ovens, fired with pulverized coal, are in use, by means of which two anneals per week are possible.

The latest type (1937) of heat-treating unit is the radiant tube, batch or continuous oven with controlled atmospheres, which do not oxidize or decarburize. In these, because of the accurate temperature control, much shorter heat treatments are possible than in any other type. The castings are not packed in pots, but are laid on trays.

**PHYSICAL CHARACTERISTICS OF MALLEABLE CASTINGS.**—In connection with tensile properties, it is the practice of the Malleable Iron Research Institute (formerly the Am. Malleable Castings Assoc.) to submit to their consulting engineer for test, a standard test bar from each day's run. Based on the average results for the years 1928-1932, the approximate physical properties were: Ultimate strength, 54,000 lb. per sq. in.; yield point, 36,000 lb. per sq. in.; elongation, 19.00%. In 1931, the A.S.T.M. and the Am. Foundrymen's Assoc. published jointly a symposium on malleable iron castings, from which the average properties in Table 1 are quoted.

**The Electrical Properties** of malleable iron lie about midway between those of cast iron and cast steel. The permeability curve lies below that of cast steel and above that of cast iron. The electrical resistance of malleable iron is about 0.000044 ohm per cu. cm. compared with the resistance of cast iron of 0.000009 ohm per cu. cm. Malleable iron possesses high induction, and both a low hysteresis loss and coercive force.

**EFFECT OF SKIN ON STRENGTH OF MALLEABLE CASTINGS.**—A popular but erroneous belief is that the removal of the so-called skin of malleable iron so reduces its strength that the machined castings are more or less worthless. These conclusions must have been based upon experiments on bars that either were unsound, due to the presence of a central shrink, or were more or less worthless even with the skin on. Results of experiments made by the author and by others, prove conclusively that the removal of the skin does not affect the strength of malleable castings of good quality.

The following tests were made by Frazer & Jones, Syracuse, N. Y. A set of 4 bars each was cast from 4 consecutive heats. Each bar had the dimensions of the A.S.T.M. standard tensile test bar, excepting that 3 had diameters in the gage length of $^3/_4$, $^7/_8$ and 1 in., respectively, instead of the $^5/_8$-in. standard diameter. These bars were machined to a gage length diameter of $^5/_8$ in. Table 2 shows results of physical tests made on these bars by Halcomb Steel Co., Syracuse, N. Y. Only the gage length of the finished bars was machined and, therefore, it is practically certain that the machined surface of the test bar ends fitting the grips of the testing machine was not parallel with the machined gage length. Consequently, the pull on the machined bars was properly more or less eccentric and results are lower than if the bars had been properly prepared for tests.

Table 3 is a record of tests made by Robt. W. Hunt & Co., Chicago, on another set of bars cast by Frazer & Jones.

**EFFECT OF THICKNESS OF SECTION ON STRENGTH.**—Based on tests made on round sections only, it can be stated that as the diameter increases, the ultimate strength, yield point and elongation all decrease slightly. With rolled steel or forgings the same is true, except that the elongation is not lowered and may increase slightly. However, malleable iron has an advantage over the other two products, in that it is of equal strength in every direction, while with rolled or forged steel the mechanical properties are appreciably lower in samples cut crosswise of the principal direction of the flow of metal. No tests have been made on flats because, as in the case of steel also, the results are greatly influenced by each change in the ratio of thickness to width.

**SHOCK RESISTANCE OF MALLEABLE CASTINGS.**—Malleable cast iron has high shock-resisting properties, due to the grain size in every part of the casting being

very small irrespective of the size of section, although slightly larger in the heavy than in the light sections. The shock-resistance is measured by the impact test used by the Malleable Iron Research Assoc. which was suggested by Benjamin Walker of the Erie Malleable Iron Co. The test can be quickly conducted and has the advantage of using cheap test specimens consisting of a wedge 6 in. long × 1 in. wide, tapering from $^{1}/_{2}$ in. at the base to $^{1}/_{16}$ in. at the thin end. The wedges are held upright at their base on the anvil of the testing machine and a weight of 21 lb. is dropped 3.33 ft. on the thin end of the specimen, causing it to curl; the procedure is continued until fracture occurs. The blows required to cause fracture are recorded and the length of the butt is measured. The length furnishes a comparative idea of the stiffness of the metal, *i.e.*, assuming that it required, in each case, 25 blows to cause two wedges to fail, the one having the longest butt would be the stiffer. This test is of extreme severity in that the blows must be resisted by sections that are very small, the extreme base of the wedge being but $^{1}/_{2}$ sq. in., while the first blow is resisted by a section only slightly larger than $^{1}/_{16}$ sq. in. If the wedge does not fail under 30 blows, the testing is stopped on the ground that a wedge withstanding 30 blows is A-1 material, and to prolong the test would serve no useful purpose.

The foundries make no use of the notched bar test, first because there is no agreement among mechanical engineers as to what actually is shown by this test, and second, because malleable iron castings are not notched. Cast specimens for the notched bar test are difficult so to gate that they will be absolutely sound. If even incipient unsoundness is present, the results will not be trustworthy. On the other hand, the wedges used for the wedge test can be cast sound; they are not notched, and the test is a fair one as indicating the toughness of the metal.

**Machining Properties of Malleable Castings.**—The fact that malleable iron can be machined at depths of cut, feeds, and speeds not possible in the case of any other ferrous metal of equal mechanical properties is freely acknowledged. While a few manufacturers of malleable iron have advanced the claim that a high tensile product cannot be machined quite as rapidly as one of lower strength, the author has attempted to determine by service tests during the years 1928 to 1932, if there was any justification for this statement. A hundred castings of low, medium and high carbon were machined at an automobile plant. Although the machine tool was run exactly in accordance with the usual practice in machining this particular casting, the machinist was unable to differentiate between the three grades. According to L. J. Kelly (*Trans.* A.F.A., 1930, p. 242), the following were the machining operations on 2 $^{1}/_{4}$-in. grease plugs cast from a hard iron of about

2% carbon: Two cuts to remove $1/4$ in. of stock; an undercut both front and back in one operation, after which the plug was threaded for a distance of $5/8$ in. As to tool life, 500 were machined every 22 hours (day and night) with but one grinding of tools; 20,000 were threaded with but three grinds of the chasers, the grinding necessary being very slight.

The author has been unable to find, during a 5-year investigation, one instance where the piece rate, set by rate-setters, has had to be altered, when the source of supply was changed from a plant making low-strength castings, to one making a high-strength product. If there is any difference, it apparently cannot be ascertained under service conditions, and no worthwhile proof has been furnished that it has been ascertained in any other manner.

Poor machinability of malleable castings results from: 1. A deep decarburized skin; such a skin mineralogically is very soft but is hard to machine, being similar in character to pure copper and pure aluminum. 2. A skin consisting of pearlite or of a layer of pearlite and ferrite, or of pearlite and free cementite, will be hard to machine, because of mineralogical hardness. The metal under the skin may be easy or difficult to machine, being easy in the majority of cases. If, however, during the anneal, the product has been heated to too low a temperature or to too great temperature for too short a time, or both, the structure will contain considerable free cementite and, therefore, will be hard to machine, depending on how seriously the correct laws of annealing have been violated. If the annealing oven has been incorrectly designed, the temperature not being uniform throughout, castings that are easy and others that are difficult to machine may be obtained from the same oven. Further, certain hard iron compositions cannot be annealed in such a manner as to yield a structure that will machine with ease. Also, annealing carried out at too high temperature will make the product difficult to machine, due to the formation of pearlite, under certain conditions, in the structure.

**HARDNESS TESTS OF MALLEABLE CASTINGS.**—Whether or not malleable iron, when machined, will test efficiently under the impact or tensile test, depends entirely on whether or not the test specimen is sound. Due to improvement in molding operations, the danger of unsound castings has largely been eliminated. Whether or not a product will machine easily or with difficulty is of first importance. Only in exceptional cases can mineralogical or cutting hardness be satisfactorily determined by the Brinell or Shore instruments. The reason for this is that during the anneal, the structure of the surface of the casting to a depth of from $1/32$ to $1/12$ in. or more will be dissimilar to the structure of the body of the metal underlying the so-called skin, which, in the majority of cases, consists of decarbonized iron, providing the pot atmosphere is oxidizing. The skin, however, may vary in structure, depending on the pot atmosphere. Under certain conditions, a skin structure consisting of 2 layers may be obtained. The outer one of these consists largely of pearlite, with perhaps some free cementite, and will be extremely hard. Between this layer and the body of the casting will be a ring of carbonless iron. This effect usually is produced through the action of an oxidizing pot atmosphere which decarbonizes the surface to a certain depth, followed by a change in the pot atmosphere from oxidizing to reducing. Under these conditions part or all of the decarbonized layer will be recarbonized, the depth depending upon the length of time the castings are exposed to this action.

In other cases, the skin will consist of an outer ring of decarbonized iron and an inner ring of pearlite and at other times of a skin consisting wholly of pearlite occasionally accompanied by considerable free cementite. The last two cases produce a fracture that is known as " picture frame " iron. The fracture shows a more or less brilliant steely frame surrounding the section and separated from it by a distinct line of demarcation. It is this character of iron that probably originated the term "black heart malleable iron" since in the early days most of the malleable iron had this type of fracture. Some writers on the subject of malleable cast iron, both in the United States and England, have presented fractures of " picture-frame iron " as representing a superior product, notwithstanding the fact that castings of such fracture would be worthless when subjected to bending or impact, the frame being hard and brittle and actually inviting fracture. It is therefore obvious that an attempt to ascertain hardness by means of either the Brinell testing machine or the Shore scleroscope would be futile. In the case of Brinell test, the ball would crush through the skin, irrespective of its character, leaving its impression partly in the skin and partly in the metal beneath. In the case of the scleroscope, the proper preparation of the specimen would involve the removal of most, if not all, of the skin.

**SHRINKAGE.**—Shrinks in castings are harmful not only because of their influence in decreasing the strength of the casting, but also due to the formation of hard spots wherever the shrink exists, which will cause trouble in machining. With few exceptions, castings can be made perfectly sound by means of large risers and heads properly located to feed the casting. With intricate patterns, it may be impossible to avoid the use of an occasional chill, due to the inability to attach a riser or a sink head in such a manner as to insure the proper feeding. The remedy lies in a change of design to meet this condition. Detection of shrinks is a most important function of the inspector, aside from confirming the strict trueness to pattern of the castings. Heavy shrinks, and even those which are less pronounced, can be detected easily by the breaking up of hard iron castings and a careful inspection of fractures at sections where shrinkage is liable to occur; that is, at fillets and at junctions of light and heavy sections. Very light shrinkage cannot be detected by this method, as such become visible only when the casting has been annealed. If castings are purchased from one of the many concerns which has paid equal attention to its furnace and annealing oven design and operation, a guarantee probably can be obtained with the product that it is free from shrink, even in cases of most complicated design. If, on the other hand, the foundry has not informed itself on the best modern practice, the product is liable to vary in composition, physical properties and machinability, while shrinks will be of rather common occurrence.

**INSPECTION.**—Irrespective of where castings are purchased, inspectors should first examine the test lugs placed upon them for that purpose. If castings are too small to warrant placing of test lugs, some castings should be broken for fracture examination as well as to test their toughness and ductility. When malleable iron fails in tension, the crystalline grains at the fracture stretch into spines, and if the product is good, the appearance of the fracture will be uniform throughout, except that there will be a slight contrast between the decarbonized surface and core. The color will depend largely upon how ductile the crystalline grains may be as well as upon composition. If the grains are very ductile and the carbon is low, the fracture will be mouse-colored. The higher the carbon content the darker will be the fracture. In correctly annealed malleable iron, if the silicon is in the vicinity of 1.10% or more, and manganese much in excess of 0.30%, or if both conditions exist, the fracture, while normal in appearance, will be more or less sparkling. This characteristic, however, is much more evident in fractures resulting from impact or when a bar is broken transversely than when fracture takes place from tension.

In the breaking of a test lug, each lug should receive as nearly as possible the same treatment. If the lug is repeatedly hit in such a manner that it will be sheared off at its base, the fracture will have a different appearance than if the blows had gradually bent the lug over and broken it in a manner similar to a transverse test. In the latter case, the fracture on the compression side will be bright to a certain depth from the surface, due to the grains having been smashed down to destruction on that side, while the side that broke in tension will show a fracture similar to what would be expected in a tension test. High carbon or high manganese or both will make the bright part on the compression side deeper. In certain cases there may be a slight shrinkage at the fillet of the lug which may affect the appearance of the fracture. If the test lugs are broken hot, that is, just as the castings are dumped from the pot, an abnormal close-grained dove-colored fracture will result that is not truly representative of the metal. Before he can gather all the information that is possible from the test lug inspection, the inspector must have had considerable experience.

A casting may be sound and the fracture abnormal, that is, the fracture may be of the picture-frame variety. It may be of steely appearance or have other faulty fracture characteristics. In such cases, the tensile test will indicate that the material is not first class. The cause of this condition usually can be ascertained by metallographic means, although sometimes a chemical analysis is also necessary. "Picture-frame" iron usually results from too low a silicon, carbon and manganese content, or from an unbalanced sulphur-manganese ratio. Steely iron can result from a low silicon or manganese content, combined, or when either is extremely low. If castings have been cooled from the annealing temperature at too fast a rate, an all-white or whitish fracture will result, the appearance depending upon the rate of cooling. The same holds true if the time of annealing has been too short or if it has been conducted at too low temperature. The cause of the trouble usually is indicated by the appearance of the fracture, or if the castings have not been held long enough close to, but under, the critical range.

**LOCATION OF TEST COUPON.**—Test pieces cut from different parts of castings of any metal are liable not to measure up to the standards of standard test bars cast from the same heat. Much, therefore, depends on the location on the casting from which the test coupon is cut. But few investigations have been conducted by the author in this connection. Such tests are hardly fair, as the specimens obviously must be cut from parts that favor solidity and from which shrink is usually absent, and also on account of the fact that the test specimens ordinarily must be of different shape than the test bar with which they are compared. In two cases, a $^1/_2$-in. round specimen was secured from a web and showed an ultimate strength about 2000 lb. lower than the standard test piece, the elongation in one case being a little in excess and in the other a little lower than the test piece.

In another case, two samples of rectangular section $^3/_8 \times {}^3/_4$ in. at gage length, machined on all sides, the ultimate strength and elongation were both slightly higher than the standard test piece. One of the principal manufacturers of railway castings reports as follows: "In order to convince ourselves that sections cut from the casting would meet specifications, two column-castings were selected, and from the cope side, coupons 12 in. long were cut with the following results":

| Sample Mark | Dimensions, in. | Area, sq. in. | Ultimate Strength, lb. per sq. in. | Elongation in 2 in., % |
|---|---|---|---|---|
| No. 1 | 0.306 × 0.825 | 0.252 | 47,500 | 11.00 |
| No. 2 | 0.340 × 1.03 | 0.350 | 48,200 | 11.00 |

**SPECIFICATIONS FOR MALLEABLE CASTINGS.**—The following is an abstract of A.S.T.M. Standard Specifications (Designation A-47-33) covering two grades of malleable iron castings:

Castings shall be produced by either the air furnace, open-hearth or electric furnace process, and be free from primary graphite. Tension specimens shall be of the form and dimensions shown in Fig. 1, and shall conform to the following *minimum* requirements as to tensile properties:

| | Grade No. 32510 | Grade No. 35018 |
|---|---|---|
| Tensile strength, lb. per sq. in. | 50,000 | 53,000 |
| Yield point, lb. per sq. in. | 32,500 | 35,000 |
| Elongation in 2 in., percent | 10.0 | 18.0 |

The yield point is defined as that load under which the specimen has an elongation in 2 in. of 0.01 in., and may be determined by the drop of the beam of the testing machine or by the divider method.

A set of three tension test specimens shall be cast from each melt, suitably marked for identification with the melt. The specimens shall be placed in some one oven containing castings to be annealed. Three of these specimens shall be selected by the inspector as representing the castings in the oven from which they were taken. The castings are accepted if the first specimen conforms to requirements, or in the event that it fails both the second and third specimen shall meet requirements. If castings are rejected, due to insufficient anneal, a reanneal is permitted. The castings shall conform to patterns or drawings (a variation of $1/_8$ in. per ft. will be permitted). Injurious defects must be absent.

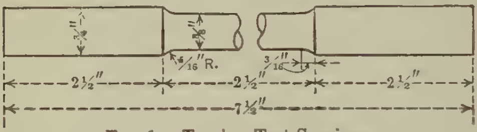

Fig. 1. Tension Test Specimen

**CORROSION RESISTANCE.**—Messrs. Wolf and Meisse (Symposium, A.S.T.M. and A.F.A., 1930) state:

1. Under the action of locomotive smoke, malleable iron shows a decided superiority over wrought-iron, basic open-hearth steel, and commercial pure iron. 2. Copper additions in malleable iron up to 2% have been found to materially increase its resistance to corrosion in locomotive smoke. 3. Copper additions to malleable iron decrease its resistance to corrosion in acid mine water. 4. Malleable iron without copper, protected by a hot-dipped galvanized coating, shows a decided superiority over steel similarly protected, after a service of 17 years in an atmosphere contaminated by smoke. 5. A hot-dipped galvanized malleable iron, with and without copper, shows a heavier iron-zinc alloy layer than either wrought-iron, basic open-hearth steel, or commercial pure iron, when galvanized under identical conditions.

Inasmuch as accelerated laboratory tests have been discredited as reflecting what might be anticipated under service conditions, coupled with the fact that field tests require years in order to secure results, the Malleable Iron Research Institute has endeavored to obtain sufficient satisfactory evidence, of a character that could not well be refuted, through examination of existing built-up parts that have been exposed for many years under various conditions. To date (1937) numerous examples have been photographed, among them heavy fences built of steel pipe with malleable iron fittings, that show, after 20 years of exposure to the atmosphere, the steel rusted through in many places and the fittings remained unaffected. Numerous other examples could be cited of steel pipe laid underground, the steel being corroded through while the malleable fittings show a surface corrosion only.

# NON-FERROUS FOUNDRY PRACTICE

By N. K. B. Patch

The production of bronze or brass, or other non-ferrous castings under modern (1937) requirements for their satisfactory service demands much higher specialization in this branch of the foundry industry than was the case only a few years ago. Metallurgical research and the development of metals of high purity both have influenced improvement in quality and uniformity of this type of castings. Skill of an increasingly higher order is demanded in order to insure the right kind of product. The old-fashioned brass foundry, commonly a corner in the iron foundry, casually attended by a practical man, who, by his own admission, was " skilled in the arts of metal " is passing. Instead, castings are purchased from foundries organized to produce uniform castings from the highest quality of modern metals.

**GENERAL.**—Non-ferrous castings being produced of materials of relatively high cost, foundry practice should be much more precise than where the metal is cheap and where much of it may be wasted without undue loss in machining. Hence, patterns for non-ferrous castings generally are made with the minimum allowance for machining. Molders should be trained to rap patterns only just enough to remove them from the sand, and also should be trained to make the molds as accurate to the pattern as a high degree of skill will permit. Uniformity of wall thickness, accuracy of casting to pattern and similar characteristics all are desirable in non-ferrous castings, not only to save the high-priced metal, but also to standardize all the different elements connected with the production of castings to a point that insures uniform quality and a material reduction in defective castings. These elements include pouring temperature, melting practice, cores and core mixtures, and the time of shaking the castings out of the mold.

## 1. MELTING EQUIPMENT

In the brass foundry, melting equipment is of first importance. Improper melting is the cause of many defective castings that heretofore have been attributed to bad molding or other causes.

**TYPES OF FURNACES.**—Three general types of furnaces regularly are used:

1. Crucible furnaces in which the metal is contained in crucibles during melting and pouring.
2. Hearth furnaces, burning solid fuel, oil, or gas, and in which the metal is melted on a hearth.
3. Hearth furnaces, which use the heat radiated from an electric arc to melt the metal.

The crucible furnace is the more common, since it entails a much smaller original investment that the other types and requires less experience and study for proper handling. The source of heat in crucible furnaces may be oil, gas, coal or coke. Furnace manufacturers should be consulted concerning the proper type of equipment for a given set of melting conditions. In small foundries producing castings weighing up to 10 lb., crucibles holding 100 to 150 lb. per charge are the most common. These require only a medium-size furnace and are readily carried from furnace to mold. For large castings, larger charges are melted and larger crucibles are necessary. Overhead equipment then must be provided to move the molten metal from furnace to mold.

Fig. 1 shows the usual arrangement of a battery of pit furnaces for crucibles. Dimensions are given in Table 1. The thickness of the refractory lining used will vary, but generally is 4 1/2 in. Many foundrymen prefer to line the iron shell with an insulating material before inserting the refractory lining. Flue sizes must be increased above those given in Table 1, if the distance from the furnace to the main flue tends to retard easy flow of gases. Where crucibles smaller than No. 20 are used, it frequently is more convenient to use a furnace that will accommodate two or three crucibles, or more. Above No. 20 size, only one crucible is inserted in the furnace, and is surrounded with the fuel. Table 2 gives dimensions of standard crucibles.

Gas or oil commonly is used as fuel, although coke or coal sometimes is used. If coal or coke is to be used for the production of heat, a well designed flue from the furnace to the chimney must be provided with adequate draft to insure complete combustion of the fuel. Such draft may be developed by a chimney of adequate height; or if furnaces are designed to accommodate it, forced draft may be used to good advantage.

Crucible furnaces of the tilting type are used in many foundries, with oil or gas as fuel. See Fig. 3. The fuel-air mixture is introduced into the furnace through a hole in

the side, from a stationary burner, and combustion is completed within the furnace. When the charge is melted the entire furnace is tilted to pour the metal. Dimensions and capacity of one type are given in Table 3.

Fig. 4 shows one form of double-chamber hearth furnace of the tilting type. Capacities of these furnaces range about as follows:

| | Single Chamber | | | | | | | Double Chamber | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| Furnace No. | 92 | 93 | 94 | 95 | 96 | 97 | 98 | 1 | 2 | 3 | 4 |
| Capacity, lb. | 500 | 1000 | 2000 | 4000 | 6000 | 12,000 | 24,000 | 250* | 500* | 1000* | 2000* |

* Each chamber.

**LININGS.**—The refractory linings used in those furnaces in which the metal actually makes contact with the lining should be of such material as will reduce to an absolute minimum the chemical reaction between metals, metal oxides and refractory at elevated temperatures. An acid refractory will react with many of the metal oxides to form a slag, and thus will be of relatively short life. Hence, a basic or neutral refractory is to be preferred, and will, if carefully chosen, give maximum life and consequent maximum economy in cost per pound of metal melted. It should be remembered that the different types of fuel affect the amount of reaction of this kind that occurs, since the percentage of reducing or oxidizing gases in the furnace materially affects the rapidity with which the chemical action takes place.

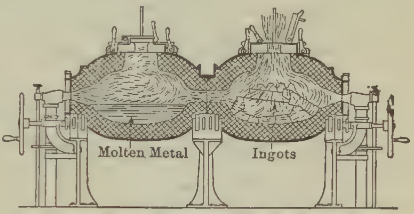

Fig. 4. Double Chamber Tilting Furnace

**MELTING TIME.**—Good practice dictates that melting must take place as rapidly as economy and good combustion will permit. This reduces the danger of gas inclusions in the metal, with resultant defective castings, and results in economy of fuel consumption. A crucible containing 150 lb. should be heated to proper pouring temperature in not over one hour, and preferably in about 45 minutes.

**CHARGING.**—The crucible should be charged first with a few gates or risers or small pieces of the metal to be melted. The larger pieces are charged on top of them. The small pieces melt first and form a puddle in the bottom of the crucible which rapidly dissolves the balance of the charge, thereby increasing the speed of melting.

**MELTING OF LIGHT ALLOYS.**—Light alloys, as aluminum- or magnesium-base alloys are melted in a cast-iron or steel bowl. These bowls are so located that the hot gases produced by the combustion of the fuel flows around them. The metal is dipped from the bowl with small ladles to be transported to the molds. The surface of the metal is kept covered with the proper type of flux, and the temperature (see Table 3) of the metal is controlled carefully by pyrometers, so located as to indicate at all times the exact temperature of the bath of metal. The furnace operator then may control the fire to insure the desired uniformity of temperature. These alloys dissolve iron from the bowl, and should not be permitted to remain therein long enough to absorb more than the maximum permissible Fe content.

To insure rapid changing of the contents of the bath of metal, the proper size of bowl must be chosen with relation to the amount of metal demanded for the kind of work produced. Where large castings are made on a mass production basis, larger bowls are used, but the metal is dipped out so fast that it is being constantly changed by the replacement of fresh metal. Consequently the metal is in contact with the iron only for a very short time. Where smaller castings are produced, and particularly where fewer molds are being poured, the demand for metal is materially less, charges are smaller, and smaller bowls are used. The metal thus is changed practically as frequently as in the first instance.

**ELECTRIC FURNACE PRACTICE.**—In the production of bronze or brass castings by means of electric furnaces, the correct size furnace for the requirements of the product is important. If castings weighing 150 lb. or more are to be regularly made, a 1-ton furnace is necessary. For castings of smaller sizes, a 250-lb. furnace will be found the most desirable. Where a variety of alloys is to be produced, several furnaces are absolutely necessary, so that a different hearth may be available for the different types of alloys. An alloy from which zinc is to be excluded should not be melted on a hearth that has previously melted an alloy containing much zinc. Aluminum-bronze, for example, should not be melted on a hearth where alloys containing lead, tin, or zinc have been melted previously; nor should phosphor-bronzes be melted on hearths previously used for aluminum-bronzes. All contamination must be avoided. This is one reason for the wide use of crucible furnaces, since they permit a crucible to be used exclusively for a given alloy. Where a change of alloy is desired, it is, therefore, only necessary to change the crucible, reserving each crucible for its own specific alloy.

Manufacturers of electric furnaces should be consulted concerning the selection of the proper type or size for melting non-ferrous alloys. The kind of work influences these details, as well as the kind of alloys to be melted and the weight of melted metal required per hour. The cost of electricity also is an important factor, since in some localities the cost of current is so high that the operating cost of electric furnaces far exceeds that of fuel-fired furnaces using oil or gas. On the other hand, in some localities electric current costs are so low that the electric furnace is the ideal unit. Natural gas, when available at very low figures is the preferred fuel, if fuel cost is the primary requisite. If, however, the quality of the metal resulting from the melting process is the controlling factor, a careful survey of the availability of the different types of fuel is advisable. The cost of each laid down, available for use in the furnace, the cost of electric current, including the installation of the necessary transformers, etc., and the kind of alloys to be melted all should have careful consideration before the final choice of melting unit is made.

## 2. MELTING TEMPERATURES

The wide variety of alloys demanded from the non-ferrous foundry prevents precise definition of proper pouring temperatures. A variation in the proportions of the different elements in an alloy changes its fluidity at a given temperature, *i.e.*, changes the proper pouring temperatures.

**INFLUENCE OF COMPOSITION ON MELTING TEMPERATURE.**— There are a number of types of alloys commonly used in the modern brass foundry. One of these, known as the 85–5–5–5 type, is specified as 85% Cu, 5% Sn, 5% Pb, 5% Zn. As produced in different plants, it often varies from these proportions. Copper may range from 86% or 87% to 82% or 83%. This change in copper content, the element of highest melting point in the alloy, would necessarily change the temperature at which the metal is sufficiently fluid to pour a given class of work. The presence of oxides entangled in the bath of molten metal also influences fluidity.

Another alloy is the 80–10–10 type, specified as 80% Cu, 10% Sn, 10% Pb. This alloy is supposed to have no zinc. However, in the regular product of many plants some zinc not only is allowed, but, in some instances, is demanded. Copper is allowed as high as 83% or 84%, or as low, in some instances, as 75%. Tin is maintained relatively close to 10%, so far as maximum is concerned, but its minimum limit is frequently as low as 7%. Since tin is the high-priced ingredient, the maximum generally is preserved and the minimum is allowed to creep rather low, in order to make an imaginary saving. Zinc frequently is permitted to make up for a reduction in tin, although it does not accomplish the same end, particularly where a hard bearing crystal is demanded. The pouring temperature of this alloy, therefore, will vary within a considerable range because of the permissible changes in the composition as produced in different plants.

Manganese-bronze, which is an alloy of copper and zinc, with some iron, aluminum, tin and manganese, is allowed to change within rather marked limits. Therefore, the pouring temperature also may vary for this type of alloy. Since this alloy contains about 40% Zn, and consequently much less copper than the two types of alloys previously discussed, the pouring temperature is much lower than the other two.

Aluminum-bronze is an alloy of copper and aluminum, in which copper predominates, but in which the aluminum content may range from 5% or 6% to as high as 11%. Iron may range from as high as 4% or 5% to approximately 1%, or none. The presence of iron tends to raise the melting point. The higher the aluminum content, the lower will be the melting point. Consequently, the pouring temperature again will vary within fairly wide limits for this type of alloy. In the aluminum-base alloys there are so many combinations of elements with aluminum that are regularly poured, that to prescribe a precise pouring temperature is impossible. The same is true of magnesium-base alloys.

It is evident that the proper pouring temperature for each non-ferrous alloy depends on the metallurgical control exercised in maintaining uniformity of alloy. Foundries producing, for example, 85–5–5–5 alloy that is relatively accurate to the specification, can, with very little experimenting, determine the preferred pouring temperature for the alloy necessary for the type of work they are required to produce. Hence, good foundry practice demands metallurgical experience and study to handle the different alloys and to pour them at their proper temperature in order to thereby secure the most desirable characteristics and the minimum number of defective castings.

It is recommended that standardization of the type of alloy to be used in a given foundry be carried as far as possible. Where special alloys are required from a foundry regularly producing a standard alloy, the foundry frequently can purchase advantageously

**Table 4.—Pouring Temperature Ranges for Various Types of Alloys**

| Type of Alloy | Range of Pouring Temperature |
|---|---|
| 85 Cu, 5 Sn, 5 Pb, 5 Zn | 1950 to 2300° F. (See Note 1) |
| Leaded bronze without zinc, 80 Cu, 10 Sn, 10 Pb type | 1500 to 2050° F. (See Note 2) |
| Manganese-bronze type | 1830 to 2100° F. (See Note 3) |
| Aluminum-bronze type | 1950 to 2250° F. (See Note 4) |

Note 1. Where this composition is departed from materially, the pouring temperature necessarily changes, but a little experience will soon indicate the desired temperature for the work in hand.

Note 2. With this type of alloy, varying as it does from 30% Pb down to 10% Pb, or even less, and sometimes containing a little zinc, the pouring temperature necessarily must range within the wide limits indicated. When it contains the upper limit of lead, the pouring temperature is lower than where the lead content is less or where some zinc is present.

Note 3. The pouring temperature of this alloy varies within the limits indicated because there are wide variations of mixtures known as manganese-bronze. See pp. 4–18 to 4–23. Some of these contain 2% Fe and some only 1% Fe. Some contain upwards of 3% Al, some only a fraction of 1% Al. The temperature for the range indicated, however, will cover satisfactorily pouring temperatures for the range of alloys in this class.

Note. 4. The aluminum-bronze standard formulas call for a range of alloys containing varying amounts of iron and aluminum (see pp. 4–18 to 4–23), and as in the case of the manganese-bronzes, the variation in the content of these materials changes the melting point and consequently the desired pouring temperature. The range given, however, will be found to be reasonably satisfactory for the average class of work.

such castings from another foundry in which these special alloys are standard and which, therefore, is better equipped to produce the highest quality of special-alloy casting.

In general, the pouring temperatures of Table 4 are for average classes of work. For castings with very thin sections, say up to 1/8 in. thick, of course, the higher pouring temperature is necessary. Where this condition exists, pouring temperatures may be reduced by providing a number of gates. In any event, pouring temperature should be no higher than is absolutely necessary. Likewise, with very heavy sections or large castings, say over 25 lb., with consequently greater mass, pouring temperatures may in some instances be even lower than those in Table 4.

## 3. MOLDING

Molds for non-ferrous castings are made by much the same process as for gray iron castings. The sand should be somewhat finer. Standard No. 00 Albany molding sand is almost universally used for the production of medium- or light-weight sand castings of brass or aluminum-bronze. However, molds for non-ferrous castings should not be rammed as hard as those for gray iron. (See p. 20–33.) Venting should be very carefully done to insure the free exit of all gases from the mold.

**CORES** used for non-ferrous castings are quite different from those used for gray iron. The higher temperature at which gray iron is poured tends to burn bonds that are only charred by the lower temperature of the non-ferrous alloys. Further, the shrinkage of many non-ferrous alloys is much greater than that of the usual gray iron alloys. Consequently, to avoid stressing castings to the cracking point during solidification and cooling, cores must permit the castings to shrink. The core binders used, therefore, should be those which will hold the sand together satisfactorily, and yet will break down sufficiently under available temperature to allow the cores to give way as shrinkage stresses develop. Cores for gray iron castings are very hard, but the binder is well burnt by the elevated temperature of the iron. Similar cores for bronze or brass castings, and even more so for aluminum castings, would be almost impossible of removal from the castings. Also they probably would not be sufficiently affected by the temperature of the metal to destroy the bond and permit the casting to shrink.

Cores for non-ferrous castings, particularly of bronze and brass, generally are made from sands mixed with a very small portion of oil binder or molasses binder, or similar type of binder. See Core Mixtures, p. 20–33. If the cores are well baked, and the absolute minimum amount of binder having been used, a minimum amount of heat will affect the binder and reduce the core to loose sand after having been subjected to the temperature of the molten metal. Where heavy walls of non-ferrous metal surround the cores, the quantity of heat available obviously is such that combustion of the core binder is much more vigorous. Consequently, the core should be somewhat harder. Where heat is available to attack the core sufficiently to cause it to scab or give trouble, the cores frequently are coated with a graphite wash, as in gray iron practice. The wash should not be thicker than is absolutely necessary. It preferably should not cause flowing by reason of having been thick, or so closely bonded, as to preclude the passage of gases through it to the core vent.

**SHRINKAGE.**—Many non-ferrous alloys are extremely brittle at a red temperature, or at the temperature at which they are just set, but before they have reached their full hardness. Shrinkage begins at this temperature and the castings, consequently, will crack if the cores do not permit shrinkage. Therefore, where very thin wall castings are made of brittle alloys, the correct choice of core binder is important if shrinkage cracks are to be avoided. In some instances, particularly aluminum-base alloys, the core binder is a thin solution of glue. This softens readily and burns quickly, and thus relieves casting strains. This is an example of the extreme that may be necessary to provide for shrinkage in extraordinary cases.

## 4. PERMANENT MOLD CASTINGS

The production of non-ferrous castings in metal or permanent molds is a specialty that has become most highly skilled and very carefully organized. The use of permanent molds for certain types of castings, particularly, aluminum-base castings, requires a high degree of experience and skill. Consequently, they should be used only by those who are competent to handle them. Similarly, die-castings are non-ferrous castings produced in dies, made by those who understand their production, and cast under pressures controlled by special machines designed to meet special conditions.

At the present state of development (1937), the die-casting process and the metal mold process are differentiated by the fact that in die-casting, the metal is forced into the mold under pressure, whereas it enters the mold by gravity in the metal mold process. The molds are similar, but obviously must be different in design, since in the die-casting process, the pressure on the metal compensates to some extent for the shrinkage of the alloy during cooling. In the metal mold process, the shrinkage must be compensated by risers, shrink balls, or similar means.

The production of centrifugal castings likewise is a specialty which is highly developed. It calls for knowledge and skill that includes a knowledge of the kind of alloys cast and of the proper design of molds, machines and the forces connected with the centrifugal casting of metals.

## 5. CLEANING CASTINGS

Cleaning or snagging in the non-ferrous foundry is much the same process as in iron and steel foundries, except that sand blasting or shot blasting is done at lower pressures to avoid injury to the surface of the casting. Risers usually are removed by band saws or hack saws. Sprue cutters also are used to advantage to remove gates or risers from castings with thin gates. Water tumbling may be used to clean some brass or bronze alloy castings, where the finish thereby derived short-cuts the final finishing process. If polishing is desirable, leather chips, or in some cases wooden chips, are placed in the tumbling barrel with the castings. Cleaning and polishing then is accomplished in a single operation.

In foundries producing non-ferrous castings exclusively, grindings from the grinding wheels contain considerable brass and bronze. These grindings should be saved and sold for their metal content. If non-ferrous castings are a very small proportion of the total production of an iron foundry, and the non-ferrous grindings are mixed with iron grindings, no credit will be given for the non-ferrous grindings. It, therefore, is desirable to so organize the foundry that non-ferrous grindings can be separated, and the value of the copper content realized.

## 6. DESIGN OF NON-FERROUS CASTINGS

In the design of non-ferrous castings engineers will do well to bear in mind that many alloys shrink rather more than gray iron castings. All of them shrink somewhat during solidification. Therefore, where thick sections join thin walls, proper fillets of ample size should be provided. In other words, transition from a thin wall to a thick wall should be as gradual as possible. Heavy bosses or lumps on castings should be avoided if soundness is to be maintained, particularly if such heavy sections are at points where proper feeding to take care of shrinkage is difficult. If possible, engineers should submit preliminary designs to competent non-ferrous foundrymen for criticism and for suggestions from the foundry standpoint before a final design is adopted. This almost invariably will avoid many pitfalls that otherwise would cause much trouble and probably large expense. It also is desirable to discuss pattern design with the foundry. Plans then may be formulated to produce the most desirable patterns from the standpoint of foundry cost and insurance against defective castings.

# THE MACHINE SHOP

Progress in the development of machine tools is so rapid that it is impossible to give details concerning the construction and operation of the many standard and special forms of lathes, milling machines, planers, shapers, boring mills, drilling machines, and other tools. The reader is referred to the catalogs of manufacturers for the latest information on this subject. The following pages cover mainly the fundamental practices underlying the operation of the various standard machine tools.

# LATHE WORK

## 1. GENERAL

**SPEED OF CUTTING TOOLS.**—The following formulas give the relations of the diameter of a rotating tool, or piece of work, number of revolutions, and cutting speeds. Let $d$ = diameter of rotating piece, in.; $n$ = revolutions per minute; $S$ = speed of circumference, ft. per min. Then

$$S = (\pi d n/12) = 0.2618\, d n \quad [1]$$

$$n = (S/0.2618\, d) = 3.82\, S/d \quad [2]$$

$$d = 3.82\, S/n \quad [3]$$

Table 1 gives the revolutions per minute for various diameters of work or tool over the range of cutting speeds commonly used in the machine shop.

**LATHE CHANGE GEARS** for screw cutting may be selected as follows:

**Simple-geared Lathes.**—Let $G_s$ = number of teeth on stud gear; $G_d$ = number of teeth on lead-screw gear; $T_s$ = number of threads per inch on lead-screw; $T_c$ = number of threads per inch to be cut. Select any gear for $G_s$. Then

$$G_d = (G_s \times T_s)/T_c \quad [4]$$

If the result is a fractional number, select another gear for $G_s$ and repeat the calculation. This equation assumes that the stud rotates at the same speed as the spindle. If these speeds are different, divide by the ratio of stud speed to spindle speed.

**Compound-geared Lathes.**—Let $G_{1r}, G_{2r}, \ldots G_{nr}$ = number of teeth on driving gears; $G_{1d}, G_{2d} \ldots G_{nd}$ = number of teeth on driven gear; $T_s$ = number of threads per inch on lead-screw; $T_c$ = number of threads per inch to be cut. Select at random all of the driving gears and also all of the driven gears except the last one. Then

$$G_n = (T_c \times G_{1r} \times G_{2r} \times \ldots G_{nr})/(T_s \times G_{1d} \times G_{2d} \times \ldots G_{(n-1)d}) \quad [5]$$

**Metric Screw Threads** may be cut on lathes with inch-divided lead-screws, by using change gears with 50 and 127 teeth, since 127 cm. = 50 in., and 127 × 0.3937 = 49.9999 in.

**THE SPEED OF COUNTERSHAFT** of a lathe is determined by assuming a slow speed with the back gear, say 6 ft. per min., on the largest diameter that the lathe will swing.

Example.—A 30-in. lathe will swing 30 in. = say, 90 in. circumference = 7 ft. 6 in.; the lowest triple gear should give a speed of 6 ft. per minute = 7.5/6 = 1.25 r.p.m.

**TURNING TAPERS IN A LATHE.**—Tapers can be turned in a lathe either by means of a taper attachment, which is supplied by many lathe manufacturers, or by setting the tailstock center a certain distance out of line with the headstock center. No rule for setting over the center can be given that will be exact, because the centers enter the work an indefinite distance. An approximate rule is: Divide the difference in diameters of the large and small ends of the taper by 2. Multiply the quotient by the ratio of the total length of the shaft to the length of the taper portion.

**SHAPE OF LATHE TOOLS.**—See Single-point Cutting Tools, pp. 21–07 to 21–27. For shapes of tools for aluminum and other non-ferrous metals see discussion of the various metals in other pages of this book.

**LUBRICANTS FOR LATHE CENTERS.**—*Machinery* recommends as lubricants for lathe centers to prevent cutting or abrasion: 1. Dry or powdered red lead mixed with a good mineral oil to the consistency of cream. 2. White lead mixed with sperm oil, together with enough graphite to give the mixture a dark red color. 3. One part graphite, four parts tallow, thoroughly mixed.

**Table 1.—Cutting Speeds of Turned Work, Milling Cutters, and Drills**

| Diam., in. | Feet per minute | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | 20 | 30 | 40 | 50 | 75 | 100 | 125 | 150 | 175 | 200 | 225 | 250 | 300 |

## 2. DRIVES, FEEDS AND SPEEDS

**DRIVES.**—The methods in common use for driving lathes and other machine tools are: Cone pulleys, usually with one or more sets of back gears; geared heads, driven by a single-speed pulley or electric motor, giving from 12 to 16 spindle speeds; individual electric motor, with a variable speed drive interposed between it and the machine. On belt-driven machines, the number of speeds available can be increased by the use of a two-speed countershaft. Speeds usually are in geometric progression. For the details of construction of the drives of a wide variety of machine tools, see O. W. Boston, Engineering Shop Practice (John Wiley & Sons).

**PROPORTIONING MACHINE TOOL GEARS IN GEOMETRIC PROGRESSION.** (C. C. Stutz, *Am. Mach.*, Jan. 15, 1920.)—**Notation.**—$a$ = slowest speed; $b$ = highest speed; $n$ = total number of speeds; $n - 1$ = total steps or intervals between total number of speeds; $f$ = ratio between successive speeds, or factor for obtaining next higher speed; $d$ = number of steps in cone pulley.

The speeds form the algebraic series, $a$, $af$, $af^2$, $af^3$ . . . $af^{n-2}$, $af^{n-1}$.

Since $af^{n-1} = b$, $f^{n-1} = b/a$, and $f = \sqrt[n-1]{b/a}$ . . . . . . . . [6]

If the desired number of speeds cannot be obtained by a cone pulley alone, back gearing, triple gearing or quadruple gearing must be used. For example, a triple-geared lathe, with a four-step cone ($d = 4$), would have the following series of speeds.

| Cone | Back Gear | Triple Gear |
|---|---|---|
| $af^{11}$, $af^{10}$, $af^9$, $af^8$ | $af^7$, $af^6$, $af^5$, $af^4$ | $af^3$, $af^2$, $af$, $a$. |

These three series bear the following relation to each other:

1. The second series can be obtained by dividing each member of the first series by $f^4$, and $f^4$ is the ratio of the back gears.
2. The third series can be obtained by dividing each member of the first series by $f^4f^4$, and $f^8$ = ratio of the triple gears.

These relations may be summarized by:

log of ratio of back gears $= d \log f$. . . . . . . . . [7]
log of ratio of triple gears $= 2d \log f$. . . . . . . . [8]
log of ratio of quadruple gears $= 3d \log f$, etc. . . . . . . [9]

When two countershaft speeds are available, the number of speeds obtainable at the spindle $= 2n$, and in this case $f = \sqrt[2n-1]{b/a}$.

We may consider that one-half of the obtainable speeds are due to the first countershaft speed, and one-half to the second countershaft speed, giving two series as follows:

$$a,\ af^2,\ af^4\ \ldots\ af^{2n-4},\ af^{2n-2}.$$
$$af,\ af^3,\ af^5\ \ldots\ af^{2n-3},\ af^{2n-1}.$$

Both series are geometrical progressions, with the same factor $f^2$. The second series can be obtained by multiplying the first series by factor $f$, which indicates that the ratio of countershaft speeds also must be $f$. The gear ratios of the machine are found by considering either one of the two series, and

log of ratio of back gears $= df^2$. . . . . . . . . [10]
log of ratio of triple gears $= 2df^2$. . . . . . . . . [11]
log of ratio of quadruple gears $= 3df^2$. . . . . . . . [12]

EXAMPLE 1.—Required the speeds and gear ratios of a 6-step cone, triple-geared; slowest speed 0.75 r.p.m.; highest speed, 117 r.p.m.

*Solution.* $a = 18$; $b = 117$; $n = 18$; $n - 1 = 17$; $d = 6$.

From [6]. $f = \sqrt[17]{117/0.75} = \sqrt[17]{156}$; $\log 156 = 2.1931246$.

$\log f = 1/17 \times \log 156 = 0.129007329$, and $f = 1.3456$.

The speeds are most conveniently found by the continuous addition of log $f$ as follows:

| TRIPLE-GEAR SPEEDS. | | BACK-GEAR SPEEDS. | | CONE SPEEDS. | |
|---|---|---|---|---|---|
| log 0.75 = 0.875061300 − 1 | = log 0.75 | 0.520097945 | | 1.294141919 | |
| log $f$ = 0.129007329 | | 0.129007329 | | 0.129007329 | |
| 0.004068629 | = log 1.009 | 0.649105274 | = log 4.457 | 1.423149248 | = log 26.294 |
| 0.129007329 | | 0.129007329 | | 0.129007329 | |
| 0.133075958 | = log 1.358 | 0.778112603 | = log 5.999 | 1.552156577 | = log 35.658 |
| 0.129007329 | | 0.129007329 | | 0.129007329 | |
| 0.262083287 | = log 1.828 | 0.907119932 | = log 8.074 | 1.681163906 | = log 47.991 |
| 0.129007329 | | 0.129007329 | | 0.129007329 | |
| 0.391090616 | = log 2.461 | 1.036127261 | = log 10.867 | 1.810171235 | = log 64.591 |
| 0.129007329 | | 0.129007329 | | 0.129007329 | |
| 0.520097945 | = log 3.312 | 1.165134590 | = log 14.626 | 1.939178564 | = log 86.931 |
| | | 0.129007329 | | 0.129007329 | |
| | | 1.294141919 | = log 19.685 | 2.068185893 | = log 117 |

The gear ratios are as follows:
Since $d = 6$, we have from [7],

log (back gear ratio) $= 6 \log f = 6 \times 0.129007329 = 0.774043974$,
whence back gear ratio $= 5.9435$,
From [8], log (triple gear ratio) $= 12 \log f = 12 \times 0.129007329 = 1.548087948$,
whence triple gear ratio $= 35.325$.

Example 2.—Required the speeds of a 4-step, back-geared cone, with two countershaft speeds; slowest speed, 25 r.p.m.; highest speed, 500 r.p.m.

$$a = 25; b = 500; 2n = 2(4 \times 2) = 16; 2n - 1 = 15; d = 4.$$

$$f = \sqrt[15]{500/25} = \sqrt[15]{20};\ \log 20 = 1.301030.$$

$$\log f = 1/_{15} \times \log 20 = 0.08673533, \text{ and } f = 1.2210.$$

Then by continuous addition of log $f$ to log $a$, as in Example 1, we obtain the series of 16 speeds as follows:

| Speed | r.p.m. | Speed | r.p.m. | Speed | r.p.m. | Speed | r.p.m. |
|---|---|---|---|---|---|---|---|
| 1 | 25 | 5 | 55.58 | 9 | 123.54 | 13 | 274.64 |
| 2 | 30.53 | 6 | 67.86 | 10 | 150.85 | 14 | 335.35 |
| 3 | 37.28 | 7 | 82.86 | 11 | 184.20 | 15 | 409.48 |
| 4 | 45.51 | 8 | 101.18 | 12 | 224.92 | 16 | 500. |

These speeds are divided into two series, each one countershaft speed.

| | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| 1st Countershaft Speed | 1 | 3 | 5 | 7 | 9 | 11 | 13 | 15 |
| r.p.m. ................ | 25 | 37.28 | 55.58 | 82.86 | 123.54 | 184.20 | 274.64 | 409.48 |
| 2d Countershaft Speed | 2 | 4 | 6 | 8 | 10 | 12 | 14 | 16 |
| r.p.m. ................ | 30.53 | 45.51 | 67.86 | 101.18 | 150.85 | 224.92 | 335.35 | 500 |

Gear ratios are: from [10], back gear ratio = $d f^2 = \log^{-1} 4 \times (2 \log f) = \log^{-1} 8 \times 0.08673533 =$ 4.9418

Countershaft ratio = $f$ = 1.2210.

Carl G. Barth (*Am. Mach.*, Jan. 11, 1912) suggests a ratio of $f = \sqrt[4]{2} = 1.189$. With this ratio the revolutions per minute of the spindle are doubled every fourth speed. An editorial (*Am. Mach.*, Dec. 3, 1914) discussing the advantage of adopting this ratio for a speed series shows that it will fulfill all the ordinary requirements of machine tool work, and that practically any desired speed in either lathe or drill press can be obtained when the machine is speeded according to a geometric progression based on the ratio 1.189.

A geometric progression of the feeds available on machine tools also is desirable, and Mr. Barth has recommended the same ratio for the feed series as for the speed series, that is, $\sqrt[4]{2} = 1.189$.

**HYDRAULIC FEEDS.**—Hydraulic feeding mechanism for machine tools has had wide application since about 1925, particularly to grinding, milling and drilling machines. The inherent advantages of hydraulic feed as compared to geared feed are stated to be as follows: The feed automatically adjusts itself to variations in depth of cut, decreasing as the cut becomes heavier, and returning to normal when the depth of cut becomes normal. This prolongs tool life and eliminates danger of tool breakage. The feed can be set for the maximum rate that the tool and machine can withstand, and can be varied by the operator from maximum down to zero without stopping the machine. Feed pressure is under control of the operator at all times. Increase of feed pressure indicates dulling of tools, and this is shown by the pressure reading and control mechanisms.

Two systems of hydraulic feed are in general use: 1. The closed circuit or variable volume system; 2. The open circuit or constant volume system. In both systems, the operating fluid either acts against a piston in a cylinder to give straight line motion to the feed mechanism, or operates some form of hydraulic motor to give rotary motion.

In the *closed circuit system*, a variable-delivery pump draws oil from a reservoir and delivers it to a cylinder to drive a piston connected to the machine table or other mechanism that is to be moved. Suitable valves, actuated by the table, control the admission and release of oil in the cylinder. Oil flows from the cylinder back to the reservoir. For rotary motion, the oil is delivered to a hydraulic motor instead of a cylinder. The pump is set to deliver only the amount of oil necessary to maintain the given rate of feed, plus unavoidable leakage. The rate of feed is proportional to the discharge of the pump, less the leakage past the pump pistons and the feed piston.

In the *open circuit system* a gear pump delivers a constant volume of oil. Such portion as is needed to maintain the desired constant pressure in the feed cylinder or motor, is delivered thereto. The balance is automatically by-passed to the reservoir. This system is particularly applicable to grinding machine tables, where the load is constant and is principally an inertia load. Applied to a drilling machine, it has the disadvantage of feeding a large drill more slowly than a small one, and dull drills more slowly than sharp ones. Further, the rate of feed can be determined only by trial, and drills jump ahead when breaking through.

For many data on hydraulic feeds, see Symposium on Hydraulic Feeds for Machine Tools, *Trans.* A.S.M.E., MSP–50–4, 1928. For data on the construction of hydraulic feed equipment, see literature issued by the Oilgear Corp., Milwaukee, Wis., and by the Cincinnati Milling Machine Co., Cincinnati.

# SINGLE-POINT METAL-CUTTING TOOLS

By Robert C. Deale

## 1. DEFINITIONS

The following definitions have been proposed (1937) to the American Standards Association. They relate to the terminology to be used in describing the construction and use of single-point metal-cutting tools for lathes, planers, shapers, boring mills, etc. For other forms of single-point tools, used largely in planers, see p. 21–30.

COMPONENTS.—**The Shank** is that part of the tool on one end of which the point is formed or the tip or bit supported.

**The Size of a Tool** of square or rectangular section is expressed by giving in the order named the width of shank, the height of shank and the total tool length in inches, *i.e.*, $3/4 \times 1\ 1/2 \times 12$ in.

**The Point or Nose** is all that part of a tool which is shaped to produce the cutting edges and face. See Figs. 1 and 2.

**The Neck** is an extension of the shank but of reduced sectional area. See Fig. 3.

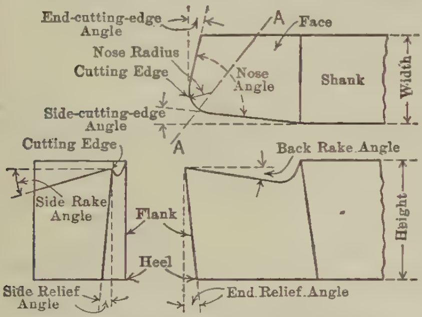

FIG. 1. Right-cut, Straight-shank Single-point Ground Tool

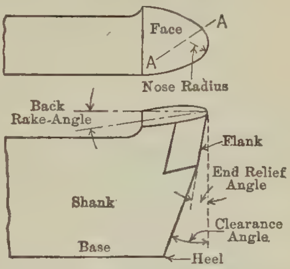

FIG. 2. Right-cut, Straight-shank, Single-point Raised Face Forged Tool

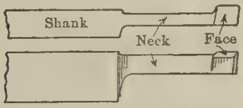

FIG. 3. Necked Tool, Forged

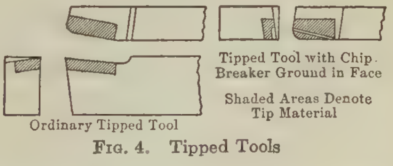


Tipped Tool with Chip Breaker Ground in Face
Shaded Areas Denote Tip Material
Ordinary Tipped Tool

FIG. 4. Tipped Tools

**The Base** is that side of the shank which bears against the support taking the tangential pressure of the cut.

**The Face** is that surface on which the chip impinges as it is cut from the work.

**The Heel** is the end of the base immediately below and supporting the face.

**The Cutting Edge,** or lip, is that portion of the face edge along which the chip is separated from the work. It consists usually of the side-cutting-edge, the nose radius and the end-cutting-edge. See Fig. 1.

**The Nose** is the curve formed by joining the side- and end-cutting edges.

**The Profile** is a plan view when looking at the face from a point at right angles to the base. It is formed by joining the side- and end-cutting-edges with the nose.

**The Flat** is a straight portion of the cutting-edge intended to produce a smooth machined surface.

**The Flank** of the tool is the surface below the cutting-edge.

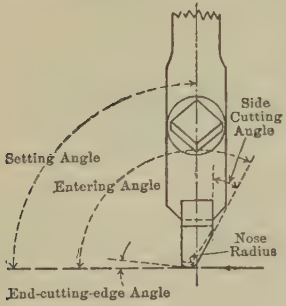
TYPES OF TOOLS.—Single-point tools may be made up as follows:

**A Ground Tool** is one in which a point is formed on the end of a bar (shank) of tool steel by grinding. See Fig. 1.

**A Forged Tool** is one in which the point is forged roughly to shape on the end of a bar (shank) of tool steel and subsequently hardened and ground. See Fig. 2.

**A Tipped Tool** is one with a tip of cutting material permanently attached to a shank of non-cutting metal. See Fig. 4.

**A Bit Tool** is one in which a small part of tool material of square, rectangular, or other section, or forged to a special shape, is held in the end of a holder or shank. See Fig. 5.



**A Tool Bit** is a relatively small piece of tool material clamped in a tool holder in such a way that it can be readily removed and replaced.

**A Right-cut Single-point Tool** is one in which the cutting-edge is on the right side when looking at the point end of the tool with the face upward and the shank pointing away.

**A Left-cut Single-point Tool** is one in which the cutting-edge is on the left side when looking at the point end with the face upward and the shank pointing away.

**An End Cut Tool** is one having its principal cutting-edge on the end.

**A Straight Tool** is one in which the point is on the forward edge of a straight shank. See Fig. 1.

**A Bent Tool** is one in which the point is bent to the right or the left. A right bent tool has the point bent to the right when looking at the tool from the point end with the face upward and the shank pointing away.

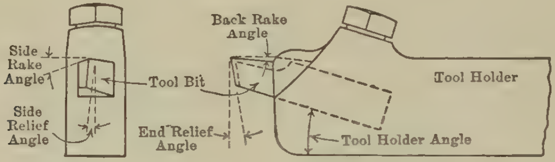


FIG. 5. Tool Bit and Holder

**The Shank Angle** is the angle by which the point of a bent tool deviates from the straight portion of the shank. See Fig. 6.

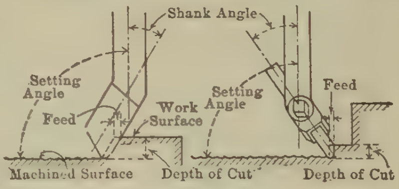

FIG. 6. Bent-shank, Single-point Tool

**An Offset Tool** is one in which the point is at either side of, but parallel to, the shank. In a right offset tool, the point is offset to the right of the shank when looking at the tool from the point end with the face upward and with the shank pointing away.

**TOOL ANGLES.**—The angles defined below are angles formed between various portions or surfaces of the tool. They are angles formed in forging or grinding the tool, and should not be confused with the working angles which mainly are angles formed between some surface of the tool and of the work.

**Back-rake Angle** is the angle between the face of a tool and the shank base, measured in a plane at right angles to the base and parallel to the center line of the nose. The angle is positive if the face slopes downward from the nose toward the shank, and negative if the face slopes upward toward the shank.

**Side-rake Angle** is the angle between the face of the tool and the shank base, measured in a plane at right angles to the base and at right angles to the center line of the nose.

**Relief Angle** is the angle between a plane perpendicular to the base of a tool or tool holder and that portion of the flank immediately adjacent to the cutting edge.

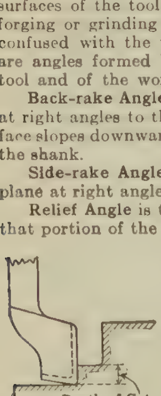

FIG. 7. Right-cut, Right-offset, Single-point Tool

**Side Relief Angle** is measured in the plane of the side-rake angle to the center line of the tool nose.

**The End Relief Angle** is measured in the plane of the back-rake angle.

**The Clearance Angle** is an angle between a perpendicular to the base of a tool and that portion of the flank immediately adjacent to the base. The side clearance is measured in the plane of the side-rake angle. The end clearance is measured in the plane of the back-rake angle.

**The Side-cutting-edge Angle** is the angle between the straight cutting edge and the side of the tool shank.

**The End-cutting-edge Angle** is the angle between the cutting edge on the end of the tool and a line at right angles to the side edge of the tool shank.

**Nose Angle** is the angle included between the side-cutting-edge and the end-cutting-edge. See Fig. 1.

**WORKING ANGLES** are those angles between the tool and work which depend not only on the shape of the tool but also on its position with respect to the work.

**Setting Angle** is the angle made by the shank of a tool with a line at right angles to the finished surface of the work. See Figs. 5 and 6.

**The Entering Angle** is the angle which the side-cutting-edge of the tool makes with the finished surface of the work. See Fig. 5.

**True Rake Angle** (or top rake) is the actual slope of the tool face from the active cutting edge in the direction of chip flow. It is a combination of front and side rake angles and varies with the setting of the tool and with the feed and depth of cut.

**Lip Angle** is the included angle of the tool material between the face and the ground flank, measured in a plane at right angles to the cutting edge. When measured in a plane perpendicular to the cutting edge at the end of the tool it is called the **end lip angle.** When measured in the direction of chip flow, it is called **the true lip angle.** See Fig. 8.

**The Working Relief Angle** is the angle between the ground flank of the tool and a line, tangent to the cut surface, passing through the active cutting edge.

**Cutting Angle** is equal to the lip angle plus the working relief angle at the point of action.

**The Working End-cutting-edge Angle** is the angle between the straight end-cutting-edge and a plane tangent to the machined surface at the point of cutting.

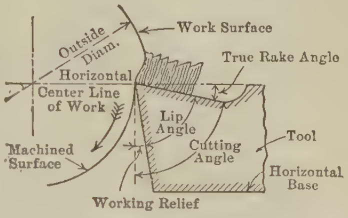

FIG. 8. Section through Plane of Chip Flow, Indicated as *AA* in Figs. 1 and 2

**CUTTING SPEED** is the peripheral or surface speed of the work with respect to the tool. In turning, it usually is measured on the uncut or work surface of the work ahead of the tool.

**DEPTH OF CUT** is the distance between the bottom of the cut and the uncut surface, measured in a direction at right angles to the finished surface of the work.

**FEED** is the relative amount of motion of the tool into the work for each revolution, stroke or unit of time.

**MACHINED SURFACE** is the surface left by the cutting tool. See Figs. 6 and 8.

**WORK SURFACE** is the surface that is to be machined. See Figs. 6 and 8.

## 2. TOOL CONTOUR AND SIZE *

**CHIP PROPORTIONS.**—The proportions of a chip, as affected by the nose contour of a tool or by the relation between depth of cut and feed, have great effect on the cutting speed which may be used. A change in chip proportions caused by a change in nose contour of the tool has the same effect on cutting speed as a similar change caused by a change in depth of cut and feed. When removing a chip of given cross-sectional area, changes in the tool contour may cause variations in the cutting speed of as much as 60%, while changes of as much as 400% may be caused by changes in the relation between depth of cut and feed.

**TOOL SIZES.**—The number of sizes of tools used in a given shop should be as small as possible. The following sizes should meet all ordinary shop requirements: *Rectangular Tools.*—$^3/_8 \times {}^3/_4$ in.; $^1/_2 \times 1$ in.; $^5/_8 \times 1\,^1/_4$ in.; $^3/_4 \times 1\,^1/_2$ in.; $1 \times 2$ in.; $1\,^1/_2 \times 3$ in. *Square Tool Bits.*—$^3/_{16}$, $^1/_4$, $^3/_8$, $^1/_2$, $^5/_8$, $^3/_4$, 1, $1\,^1/_4$, and $1\,^1/_2$ in. *Rectangular Tool Bits.*—$^3/_{32} \times {}^1/_2$ in.; $^1/_8 \times {}^3/_4$ in.; $^3/_{16} \times 1\,^1/_8$ in.; $^1/_4 \times 1\,^3/_8$ in. A relatively small number of the foregoing sizes should be ample for all except the largest machine shops.

Tool bits are available which are forged to the desired form. Such bits must be used in special holders, usually made by the company furnishing the bits. Such bits are at times very convenient for shop use, but are much more expensive per pound than bar stock. When adopting such tools and holders, both the stiffness of support to the cutting edge, and the percentage of the new tool which may be used before it is discarded should be considered.

**Effect of Tool Size.**—The size of a tool has no effect other than to give strength to the tool, to reduce deflection, or to increase the tool width available for a forming cut. A properly supported small tool may be run at the same cutting speed as a large one having the same shape, for the same depth of cut and feed.

**TOOL FORM.**—When heavy roughing cuts are to be taken, and it is desired to use heavy forged tools, there are no better shapes of tool than those developed by Carl Barth. These are shown in Fig. 9. Dimensions are given in Table 1.

Tools of the form shown in Fig. 10 are used for parting cuts. They usually are from $^1/_2$ to $^3/_8$ in. wide at the nose, except when the diameter of work to be parted is large, when they may be wider. To obtain the necessary stiffness, the cutting section of such a tool usually is forged down from a shank of comparatively large section. Note that the sides of the neck of this parting tool converge at a slight angle, usually from $^1/_2$ deg. to 2 deg., to avoid interference with the side of the cut. The side relief angle is small, usually not over 2 deg. At times a blade having a height of from 5 to 8 times its width, held in a special holder, is used as a parting tool.

* For complete data on the use of cutting tools, including feed and speed data for many varieties of alloy steel, see "Manual of Metal-Cutting," published by Am. Soc. M. E., 1939.

**Table 1.—Dimensions of Round-nose Forged Single-point Tools**

Left-cut straight tool with raised face. Barth standardization. See Fig. 9

| Tool size, in., *W* | 1/2 | 5/8 | 3/4 | 7/8 | 1 | 1 1/4 | 1 1/2 | 1 3/4 | 2 |

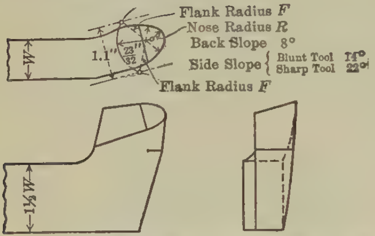

FIG. 9. Left-cut, Straight-shank, Round-nose Tool with Raised Face

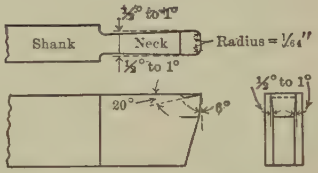

FIG. 10. Recommended Shape of Parting Tool

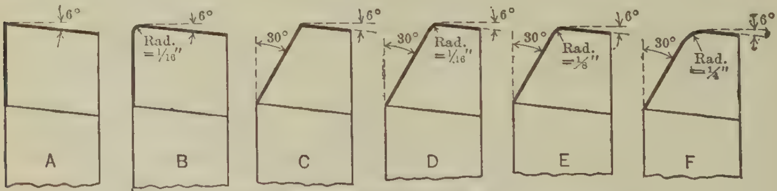
The contours shown in Fig. 11 are suitable and recommended for right-cut tool bits, or small solid tools ground directly from the bar. A similar set of tools, with the cutting edge on the right-hand side of the tool, would be necessary for cutting from left to right.

For facing operations the active cutting edge is on the end of the tool, preferably with a back rake equal to the side rake used on ordinary roughing tools, and with a side slope of approximately 8 deg. The right-cut contours shown in Fig. 12 should be ample for all ordinary operations. A similar set, with the active cutting edge on the opposite side of the tool, would be required for left-cut tools.

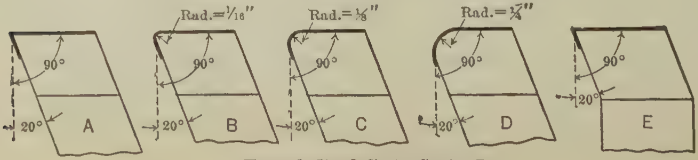
Tools for finishing cuts should have an appreciable flat on the end, substantially wider than the feed per revolution or stroke. See Fig. 13.

**RAKE ANGLE.**—There seems to be little necessity for making any considerable variation in rake and relief. While cutting pressures are decreased by an increase in rake, the cutting speed is not greatly affected by such changes. While the chip is removed with less expenditure of energy by the tool having the greater rake, the reduction in cutting angle tends to weaken the tool, and so causes failure sooner than would be the case if a smaller rake were used.



Heavy Outline Indicates Cutting Edge

FIG. 11. Recommended Contour, Right-cut Roughing Tool

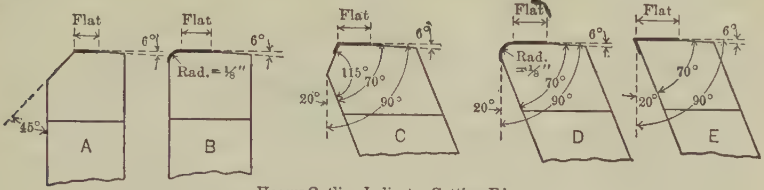


Heavy Outline Indicates Cutting Edge

FIG. 12. Recommended Contour, Right-cut Facing Tool

The values of rake given in Table 2 are based on the practice of a leading manufacturing company, for use with high-speed steel tools.

Table 3 shows the practice recommended by Fred H. Colvin and Frank A. Stanley (Turning and Boring Practice; McGraw-Hill Book Co.) for use with cemented carbide tools.



Heavy Outline Indicates Cutting Edge

FIG. 13. Recommended Contour, Right-cut Finishing Tool

## 3. CUTTING SPEEDS AND FEEDS

**ECONOMIC TOOL LIFE.**—Under a given set of conditions, it may be shown that there is a particular tool life which gives lowest overall costs. This tool life, and the accompanying cutting speed may be calculated, if all data are available. The values given in Table 5, however, may be used without great loss in efficiency.

While sufficient data are not available (1937) for exact figures, a tool life of from three to four times as great as is desirable for use with high-speed steel should be used in determining operating conditions for cemented carbide tools.

**Table 2.—Rake and Relief Angles for High-speed Steel Tools Cutting Various Metals**

| Metal Cut | Operation | Back Rake, deg. | Side Rake, deg. | Side Relief, deg. | End Relief, deg. |

Table 5 shows the effect of variations in cutting speed on tool life. This table is based on a value of unity for a tool life of 60 minutes. If the proper cutting speed is known for a cut $A$ of given duration, the speed for a cut $B$ of different duration may be obtained by the formula

$$S_b = S_a \times (F_b/F_a)$$

where $S_b$, $S_a$ = respectively cutting speeds of $A$ and $B$, and $F_a$, $F_b$ = respectively tool life factors for $A$ and $B$ from Table 5.

Example.—A cutting speed of 95 ft. per min. in rough turning steel with high-speed steel tools gives a tool life of 45 min. Required the cutting speed to give a tool life of 120 min. *Solution.*—$A = 45$; $B = 120$; $S_a = 95$. From Table 5 tool life factor $F_a = 1.04$, and $F_b = 0.92$. Then $S_b = 95 \times (0.92/1.04) = 84$ ft. per min.

**ECONOMIC PRODUCTION.**—To keep costs at a minimum in rough machining operations, the maximum volume of chips per minute must be removed. This involves: 1. The maximum depth of cut that can be taken without distortion of the part machined, up to the point where all surplus stock is removed in a single roughing cut. 2. A relatively large feed, which gives thick chips, preferably above 0.030 in. 3. The use of a tool having a contour which gives the smallest possible chip thickness for a given feed without setting up injurious chatter. Increase in the nose radius or the side-cutting-edge angle decreases chip thickness under constant conditions of feed and depth of cut. 4. A cutting speed such that the life of the tool approximates the economic life.

**MATERIALS CUT.**—Tables 6, 7 and 9 give the approximate relative machinability, based on the speed with which a given cut may be taken, of a large number of common materials. These tables may be used to determine the correct cutting speed and horsepower requirements for the various materials under a variety of working conditions, by use of the multipliers for speed and horsepower in connection with the basic data given in Tables 10 to 18. Table 6 is based on S.A.E. 1030 hot-rolled steel (see Tables 11–13). Table 7 is based on cast iron of 177 Brinell hardness and tensile strength of 30,000 lb. per sq. in. (see Tables 14 to 17).

Example.—Required the correct cutting speed and horsepower for turning S.A.E. 2330 steel, normalized, using a round-nose tool set at an angle of 30 deg. to the work, with a $^1/_8$ in. depth of cut and a $^1/_{32}$ in. feed. *Solution.*—From Table 12, the desirable cutting speed for S.A.E. 1030 hot-rolled steel, under the conditions given, is 80 ft. per min. The horsepower required at the nose of the tool is 2.5. From Table 6, the multiplier for speed for S.A.E. 2330 normalized steel is 0.68. The multiplier for horsepower is 0.65. Cutting speed for S.A.E. 2330 normalized steel = 80 × 0.68 = 54.4 ft. per min. Horsepower required at nose of tool = 2.5 × 0.65 = 1.63.

**TOOL PRESSURE.**—F. W. Taylor (*Trans.* A.S.M.E., xxviii, 1908) found that no definite relation exists between the cutting speed of tools and the pressure, tangential to the finished surface of the work, exerted on the tool by the chip.

The value of this tangential component, which is of interest in the design of machine tools is

$$P = K_1L^{1.1}T^{0.78}, \text{ for cutting steel, and}$$

$$P = K_2LT^{0.65}, \text{ for cutting cast iron,}$$

where $K_1$, $K_2$ = constants, given in Tables 6 and 7; $L$ = total width of chip, in., which for the average tool is equal to the total length of cutting edge of the tool in contact with the work (see Fig. 14); $T$ = average thickness of the chip, in. This usually equals (Feed × Depth)/$L$.

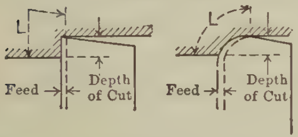

Fig. 14. Determination of Factor $L$ in Formula for Tool Pressure

**METAL CUTTING TESTS.**—Metal cutting tests, to be on a thoroughly scientific basis, require the consumption of much more time and material than usually is available in the average shop. For detailed discussion of the subject see Test Code for High-speed Steel for Turning Tools, *Mech. Engg.*, March, 1931, and Standardization of Testing Conditions for Metal Cutting Tools, *Mech. Engg.*, Sept., 1932. Also, A Metal Cutting Test Metal for Machine Shop Use, *Iron Age*, May 13, 1937.

**CUTTING SPEED TABLES.**—Tables 11, 12 and 13 are based on the cutting of S.A.E. 1030 hot-rolled machinery steel with an 18–4–1 high-speed steel tool. The horsepower given is that developed at the nose of the tool, and does not include any losses in the machine. Tables 15, 16 and 17 are based on the cutting of gray cast iron, Brinell hardness No. 177. The tools used were 18–4–1 high-speed steel tool. See Table 22.

**SPEEDS AND FEEDS FOR MONEL METAL.**—Table 8, giving speeds for Monel metal, is based on experiments by the International Nickel Co., and by Melvin Matson at Montana State College. See Melvin Matson, Lathe Cutting of Monel Metal, *Iron Age*, Sept. 10, 1936.

**TOOLS FOR TURNING MONEL METAL** should be of much the same shape as those used for turning medium steel. Because of the toughness of the chip it is particularly desirable to use a chip breaker.

## Table 6.—Machinability Constants of Steel

For analysis of the various steels listed, see p. 2–42.

| Steel, S.A.E. No. | Condition* | Heat Treatment | | | Physical Properties | | | | | Chip Pressure Constant $K_1$ | Multipliers for S.A.E. 1030 HR Values. See Tables 10 to 13 | | Relative Machinability |

## 4. CUTTING FLUIDS

The various fluids used in metal cutting operations serve the following purposes: 1. Cooling the tool; 2. Cooling the work; 3. Improving the quality of the surface produced; 4. Lubricating the surfaces in contact between the tool and work, or preventing welding of chip or work to the tool, thus aiding in reducing the temperature of the tool; 5. Flushing away the chips; 6. Reducing the pressure of the chip on the tool.

For cooling tool and work and flushing away chips, the quantity of fluid is more important than the kind. A thin soluble oil solution, approximately 40–1, or a solution of soda or borax in water is very satisfactory. A pure oil or a rich mixture of soluble oil does not appear to be so efficient a coolant as a fluid which is mainly water.

An oil containing a large percentage of sulphur appears to reduce the tendency of a steel chip to weld to the tool. Such oil is advantageous when a good quality of machined finish is desired. For finishing operations an oil with a high degree of oiliness generally is used.

**QUALITY OF SURFACE.**—There are few data available as to the effect of cutting fluids on the quality of the surface produced. Where high quality of finished steel surface is required, a sulphurized mineral, or a sulphurized mineral lard oil generally is used, except that water or soluble oil generally is used to obtain a high grade of finish with a spring tool on a lathe.

**EFFECT OF QUANTITY OF CUTTING FLUID.**—When a cutting fluid is used it is particularly important that it be applied steadily; intermittent application may tend to crack the tool. When machining surfaces which are not easily accessible, special means should be provided, for supplying the cutting fluid at the cutting edge of the tool; for example, oil holes through the boring bar used for boring deep holes.

Table 19, based on the work of George Schlesinger as reported in *Stahl u. Eisen*, Vol. 48, p. 341, gives an indication of the effect of variation in the quantity of fluid used on the rate of metal removal. Frederick W. Taylor had recognized the importance of an adequate quantity of cutting fluid and recommended the use of at least 3 gal. per minute on

(*Continued on* p. 21-22)

### Table 10.—Cutting Speed and Horsepower Required for Cutting Steel with Carbon Steel Round-nose Tools. Tool life, 1 hr.

Steel: S.A.E. 1030, hot rolled. Tool: 1.15 Carbon Steel; nose radius, 1/8 in.; side-cutting-edge angle, 0; front-cutting-edge angle, 6 deg.; side rake, 14 deg.; back rake, 8 deg.; clearance, 6 deg. See Fig. 11F

roughing cuts. It will be seen from Table 18 that the use of 3 gal. per min. of water results in a condition close to the maximum for the experiments on which this table is based.

For light cuts on steel, where the chip thickness is less than 0.015 in., the use of a copious supply of cutting fluid permits the use of cutting speeds approximately 16% greater than could otherwise be used. The effect of the cutting fluid appears to vary with the thickness of the chip from 16% for thin chips up to approximately 50% for chips approximately 0.090 in. thick.

**GENERAL RECOMMENDATIONS.**—Table 19 is based on experiment, and on the recommendations of the suppliers of cutting fluid. Where possible, it is advisable to obtain the recommendation of a reliable manufacturer concerning the fluid to be used for a particular application.

## 5. FACTORS AFFECTING RATE OF METAL REMOVAL

**SET-UP MATERIAL.**—Provision of an adequate quantity of well-chosen and well-arranged set-up material will save much time in making ready the average job. More time is lost on non-repetitive work through failure to provide an adequate equipment of set-up material, with racks or cabinets for keeping it in an orderly manner, than through any other failure on the part of management.

A supply of the frequently-used equipment should be kept at each machine tool. The cost is low, when compared with the reduction in set-up time made possible by a carefully engineered equipment of make ready material, and should prove to be a very profitable investment.

**EFFECT OF LENGTH OF TOOL EXTENSION.**—Tools should be so clamped in the tool post as to be supported, as closely as possible, directly beneath the active cutting edge. Excessive overhang may cause chatter and make necessary an appreciable reduction of speed, feed, or both. The following figures, based on the shop practice of a leading manufacturer of machine tools in the use of large forged planer tools, give an indication of this effect:

| Tool extension, in. | 0–8 | 8–12 | 12–20 | 20–34 | 34 and over |
|---|---|---|---|---|---|
| Reduction in cut and feed, percent | 0 | 25 | 50 | 60 | 65 |

**EFFECT OF WORK SET-UP ON RATE OF METAL REMOVAL.**—The size of chip removed and the cutting speed used depend on the stiffness of the work, the amount it overhangs the supporting surface, the amount of unbalance, and the rigidity with which it is clamped. Experience has shown that at times, when the part is weak, and cannot be solidly held, it is necessary to reduce the rate of removing metal as much as 75% over that possible with stiff, well-held work.

**EFFECT OF ATTENUATION OF WORK ON RATE OF METAL REMOVAL.**—When long, slim work must be turned on centers, the ratio between length and diameter of the work piece has an appreciable effect on the size of chip which may be taken, and on the cutting speed that may be used. Fig. 15 shows the effect on production rates of variations in the ratio of unsupported length to the diameter of the work, when cutting S.A.E. No. 1035 hot-rolled steel, with a tool having a $^1/_{16}$-in. nose radius, 90-deg. entering angle, 6-deg. nose drag angle, 14-deg. side rake, 8-deg. back rake, 6-deg. relief angle, when taking a cut $^1/_{16}$ in. deep, with a feed of 0.033 in., used for the roughing cut. The finishing cut was taken with a similar tool having a $^1/_{16}$ in. flat, with a depth of cut of 0.015 in. and a feed of 0.033 in. The curves of Fig. 15 have been used successfully, in the shop in which they were developed, for setting production rates on a variety of long slim shafts approximately 1 to 2 in. diameter, supported on centers and made in lots of 1 to 5. The extent to which they are applicable to conditions different from those for which they were developed is uncertain. They, at least, may be used as an indication of the reduction in the rate of chip production which becomes necessary as work on centers decreases in stiffness.

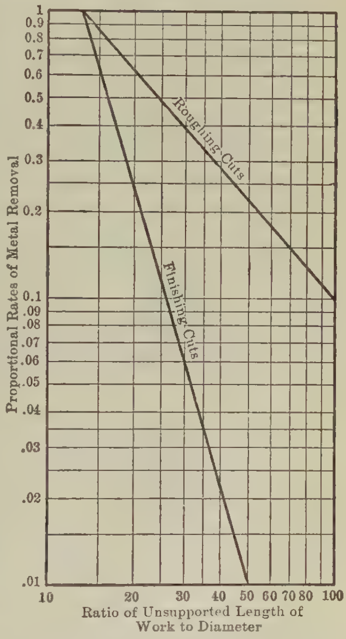

Fig. 15. Effect on Metal Removal of Ratio of Unsupported Length and Diameter of Work. Steel Work Piece Supported on Centers

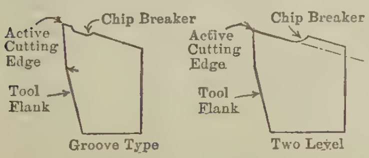
**CHIP BREAKERS.**—The chip tends to flow over the face of a tool freshly ground in the usual way as a straight ribbon, gradually changing to a helix, which decreases in radius as the tool becomes worn. These long, straight chips are difficult to handle, and it frequently is desirable to force the chip into helical form by a device called a chip breaker.

A chip breaker either may be ground into the face of the tool, or may take the form of a supplemental piece, attached to the face of the tool. Fig. 16 shows two common forms of chip breaker which are ground into the face of the tool. A chip breaker is needed only when the chip comes off in the form of a long continuous helix. It is not necessary when cutting cast iron or other metals where the chip tends to break into short pieces.



Groove Type

Two Level

Fig. 16. Chip Breakers

**CHATTER** may be affected by several variables, of which the following probably are the most important: 1. Material cut; 2. Chip proportions, as affected by *a*, depth of cut, *b*, feed, *c*, tool contour; 3. Cutting speed; 4. Rigidity of work; 5. Stiffness of tool; 6. Stiffness of work support; 7. Stiffness of tool support; 8. Vibrations caused by nature of design of machine tool, such as the gear ratios and tooth forms used; 9. Setting of tool with respect to work.

Many of these variables are fixed by the design of the part to be machined, and the machine tool available for doing the work. It appears that the best method of controlling chatter under a given set of conditions is to vary the chip proportions, cutting speed, the rigidity of the work support, or the setting of the tool with respect to the work.

**Chip Proportions.**—Study of experimental data indicates that a cut taken with a relatively thick chip has less tendency to chatter than one taken with a thin chip. It would seem that it is desirable, in order to reduce chatter, to increase the feed, or to so change the shape of tool as to increase the thickness of chip with respect to its width. A tool having a nose radius greater than half the depth of cut is very apt to cause chatter unless a heavy feed is used.

**Cutting Speed.**—A reduction in cutting speed may reduce or eliminate chatter. Some experimenters have reported that an *increase* in cutting speed may reduce chatter.

**Rigidity of Work Support.**—Use of a center or follower rest frequently will eliminate chatter. The use of opposed tools, to balance the normal components of the cutting pressure, makes a very efficient method of reducing chatter.

**Setting of Tool.**—It has been found that a change in the setting of the nose of a tool with respect to the lathe center may affect the amount of chatter. Carl G. Barth has related to the author that in an aggravated case, setting of the tool nose considerably above the work center eliminated chatter. It is believed that this elimination resulted from the steadying effect of the contact between tool flank and work.

**TOOL GRINDING.**—Improper grinding of metal-cutting tools leads to appreciable losses in production. Failure to use the most effective tool contours and angles requires a reduction in the cutting speed. Grinding of tools by the individual machine operator causes a loss in production, as the machine tool must stand idle while tools are being ground. There is a growing tendency toward the grinding of all tools in a central tool room.

* Periphery of wheel. † Cup wheel. ‡ Vitreous.

The type of grinding wheel to be used for tool grinding depends on the tool material, the area of contact between tool and wheel, whether the grinding operation is roughing or finishing, the surface of the wheel on which the grinding takes place, whether the tool is rigidly or loosely held with respect to the grinding wheel, and whether or not water is used.

Tables 20 and 21 summarize the recommendations of the two largest manufacturers of grinding wheels concerning the wheel that should be used under different conditions.

## 6. TOOL MATERIALS

The materials used for making tools for the cutting of metals may be classified in the following groups: 1. Carbon tool steel; 2. Low-alloy tool steels; 3. High-speed steel; 4. Non-ferrous alloys; 5. Cemented carbides; 6. Diamond.

**CARBON TOOL STEEL.**—A tool steel containing little or no alloying metals, and with a carbon content of from 1.10 to 1.30% is used for cutting operations where a hard, keen cutting edge is required, at low cutting speeds, particularly when a high quality of finished surface is desired. It is used at times for forming tools, particularly where it is desirable to form the tool before hardening. It also is used at times where the size of the tool or work, coupled with speeds of available shop equipment, limit cutting speeds.

**LOW-ALLOY TOOL STEELS** include the fast finishing steels, and some steels used for twist drills.

**HIGH-SPEED STEEL** is a steel containing at least 12% tungsten, 7% molybdenum or an equivalent combination of the two, together with appreciable percentages of chromium and vanadium, and, at times, cobalt. Analyses of the steels in most common use are given in Table 22. High-speed steel tools are much more generally used than those of other tool materials. They combine superior cutting qualities, strength, toughness and relatively low first cost for a very wide range of general machining operations. Cutting qualities vary with composition. See Table 23. For history of the development of high-speed steel see F. W. Taylor, The Art of Cutting Metals, *Trans.* A.S.M.E., xxviii, 1, 1908.

In general, the cobalt steels may be run at higher speeds, particularly on heavy roughing cuts. They are more brittle and weaker, when hardened to secure maximum cutting speeds, and are appreciably more expensive than the standard high-speed steels. They must be hardened at temperatures approximately 50 deg. F. higher than the equivalent standard steels. Particular care, therefore, is necessary in hardening to prevent surface burning and decarburization. The use of cobalt steel largely is confined to tools in which the contour is formed by grinding after hardening, such as lathe and planer roughing and finishing tools, tool bits, and inserted blades for milling cutters.

**NON-FERROUS ALLOYS.**—Of the several tool materials in this class, the best known are Stellite and No. 548 alloy. These materials occupy a position between the high-speed steels and the cemented carbides. They can be run at cutting speeds approximately 50% greater than those possible with high-speed steel, particularly when roughing cast iron, brass, and bronze. Their price is approximately 3 $^1/_3$ times that of high-speed steel. Tools of these materials are extremely brittle, and great care is necessary to prevent tool breakage or chipping of the cutting edge.

Many useful data on the performance of Stellite tools will be found in a paper by W. A. Becker, F. E. Gordon and W. A. Wissler, *Trans.* A.S.M.E. MSP–53–11a, 1931. They state that Stellite has been found most useful for cutting cast-iron, although it has been used successfully on steel under certain conditions. A typical cast-iron turning job ran at 87 ft. per min. with a $^5/_{32}$-in. cut and a feed of 0.05 in. per rev. The tool had a 5-deg. side rake and 6-deg. relief angle. Turning of 1020 S.A.E. steel was done at 110 ft. per min., with a feed of 0.021 in. per rev. and a cut of

**Table 22.—Materials Used for Metal Cutting Tools**

| 18–4–1 + 4% Cobalt | 0.70–0.75 | 18.0 | 0.5 | 4.0 | 1.0 | 4.0 |
| 18–4–2 + 7% Cobalt | 0.75–0.80 | 18.0 | 0.75 | 4.0 | 2.0 | 7.0 |
| 20–2 $^1/_2$–1 $^1/_2$ + 12% Cobalt | 0.80–0.85 | 20.0 | 1.00 | 4.5 | 1.5 | 12.0 |
| 14–4–2 + 4% Cobalt | 0.75–0.80 | 14.0 | 0.25 | 4.0 | 2.0 | 4.0 |
| Moly-Tungsten + 5% Cobalt | 0.80–0.85 | 1.4 | 9.0 | 4.0 | 1.0 | 7.0 |

1/8 in. The tool had 10 deg. side rake, and 7 deg. relief angle. For turning bronze at 131 ft. per min. with a feed 0.021 in. per rev., and a cut of 1/16 in., a tool with 10 deg. side rake, 10 deg. relief, and 5 deg. negative back rake was used.

**CEMENTED CARBIDE TOOLS** are made of tungsten, tantalum and titanium carbides in different proportions, cemented into a material usable for metal cutting tools by means of a matrix of cobalt. Such tools usually are in the form of small tips, which are brazed to a tool shank made of a relatively tough and inexpensive steel.

The cemented carbides are extremely hard and brittle, and may be run at cutting speeds approximately 3 1/2 times those possible with high-speed steels for the same cuts. Great care must be used to prevent chipping of the cutting edge. Such tools are particularly useful when cutting materials of low tensile strength which have an abrasive action on the tool. Carbide tools used for cutting steel usually contain appreciable proportions of tantalum and titanium carbides, which reduce the tendency of the chip to adhere to the tool.

The following tool angles are recommended for cemented carbide tools:

| | Cast Iron | | | Steel | | | Stainless | Steel Casting | | Bronze | Alum- |
|---|---|---|---|---|---|---|---|---|---|---|---|
| Material | Soft | Hard | Chilled | Soft | Hard | 12%Mn | Steel | Soft | Hard | Brass | inum |
| Lip angle, deg. | 74–80 | 74–80 | 82–60 | 60–65 | 65–74 | 80–84 | 65–74 | 68–73 | 73–78 | 65–75 | 50–55 |
| Relief angle, deg. | 5 | 4 | 3 | 6 | 5 | 4 | 5 | 5 | 5 | 6 | 8 |

For uninterrupted cuts, or for material with blowholes, etc., or where there is excessive vibration, the back rake and relief angles should be reduced to give a larger cutting angle and bring the point of support more nearly under the cutting edge.

Thomas Prosser & Sons, New York, give the values in Table 23 as good averages for cutting speeds in ft. per min., feeds in in. per rev., and maximum depths of cut, in. for cemented carbide tools.

**Table 23.—Feeds and Speeds for Cemented Carbide Tools**

¶ Surfaces containing sand and blowholes.

**DIAMONDS.**—Diamonds cut and polished to the desired contour, and set in an appropriate form of holder, are used as cutting tools, particularly when it is desired to turn or bore a part with extreme accuracy; for example, the piston rod bushings of a gasoline engine. They usually are used for cutting relatively soft materials, as bronze, hard rubber, or molded synthetic resins, which may have considerable abrasive action on the tool.

## 7. HEAT TREATMENT OF TOOL STEELS

**CARBON STEEL** used for cutting tools should be hardened as follows:

**Anneal.**—Heat to 375–1425 deg. F., and cool slowly, either in furnace or buried in an insulating material, as lime, ashes, or infusorial earth. Tools should be annealed after each hot or cold working, to reduce hardness and prevent the formation of a coarse crystalline structure.

**Normalize.**—Heat tool uniformly to 1575–1650 deg. F., until there is complete penetration of the heat and refinement of the grain, and cool in still air.

**Preheat.**—Preheating of carbon steel tools is unnecessary unless the tool is exceptionally thick, or is extremely irregular in shape. If preheating is believed to be necessary, the tool may be placed in a cold furnace which is brought slowly to hardening temperature; or it may be given a preheat of approximately 900 deg F. before being placed in the hardening furnace.

**Hardening.**—Carbon tool steel should be hardened at temperatures which vary with the carbon content of the steel, as follows:

| Carbon content, % | 0.65–0.80 | 0.80–0.95 | 0.95–1.10 | 1.10 and over |
|---|---|---|---|---|
| Hardening temperature, deg. F. | 1450–1550 | 1410–1460 | 1390–1430 | 1380–1420 |

**Quenching.**—Carbon steel tools usually are quenched in a brine, consisting of sodium or calcium chloride in water, at about 70 deg. F. They may be removed from the brine and placed in oil while still retaining a considerable portion of their heat.

**Tempering.**—The hardening of steel tends to set up internal stresses which cause brittleness and a tendency for the cutting edge to break under cut. These conditions may be relieved by tempering as follows: To relieve strains, temper in oil at 300–375 deg. F.; to relieve strains and reduce brittleness, temper in oil at 375–500 deg. F.; to relieve strains and toughen, temper in lead at 500–650 deg. F. The strength of an untempered carbon steel tool, as measured by the torsion impact test, is approximately one-fourth of its strength when tempered to develop maximum strength.

**HIGH-SPEED STEEL.—Annealing.**—All high-speed steel should be annealed before machining, after forging, or before rehardening. Pack bars or tools in annealing boxes, allowing about 1 $^{1}/_{2}$ in. between tools and sides of box, using lime, mica, infusorial earth, ashes or, at times, charcoal, as the packing medium. Each box should be sealed with fireclay, raised slowly to 1550–1650 deg. F. in the furnace, and allowed to remain at the annealing temperature long enough to anneal thoroughly. This time varies with the size of the tools and the weight of the charge; it will range from 5 to 10 hr. Boxes and work should be allowed to cool slowly in the furnace.

**Preheat.**—Because of the low thermal conductivity of high-speed steel, it usually is brought to one or more intermediate temperatures in other furnaces, before it is placed in the hardening furnace. Tools usually are brought to a temperature of 1550 deg F. in a single stage of preheat. Large, intricate tools may be heated to approximately 1000 deg. F. in the first preheat furnace, and to 1550 deg. F. in the second, before hardening.

**Hardening.**—High-speed steels must be heated to a point close to their fusion point, in an atmosphere as nearly neutral as possible, to develop maximum efficiency as metal cutting tools. This may be obtained by manual control of the fuel and air supply; by enclosing the tool in a container lined with a material which gives off carbon monoxide when heated; by heating in a closed chamber the atmosphere of which is controlled by use of an auxiliary gas burner at the door; or by use of an inert gas, such as hydrogen, in a closed furnace chamber. There is a tendency toward the use of furnaces having some method of atmospheric control.

To obtain maximum practical cutting speeds, high-speed steel should be hardened at approximately the following temperatures:

| | 18–4–1 | 18–4–2 | 14–4–2 | 18–4–1+Co | 14–4–2+Co | W–Mo | W–Mo+Co |
|---|---|---|---|---|---|---|---|
| Hardening temp., furnace, deg. F. | 2400 | 2400 | 2350 | 2450 | 2400 | 2250 | 2300 |
| Hardening temp., bath, deg. F. | 2350 | 2350 | 2300 | 2400 | 2350 | 2200 | 2250 |

High-speed tools should remain in the hardening furnace sufficiently long to make certain that they have reached a uniform temperature, and that the thermal reactions have taken place completely. For a modern furnace, in which there is little tendency to burn the surface and edges of the tool, the following times are approximately correct:

| Tool thickness, in. | $^{1}/_{4}$ | $^{1}/_{2}$ | $^{3}/_{4}$ | 1 | 1 $^{1}/_{2}$ | 2 | 3 | 4 | 5 | 6 | 8 | 10 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Heating time in furnace, minutes | 2.0 | 3.0 | 4.0 | 5.0 | 7.0 | 8.5 | 12 | 15 | 18 | 20 | 25 | 30 |

These times are based on complete penetration of the heat. It frequently is undesirable or impracticable to use hardening times as long as those required for the larger thicknesses. For very thick tools, the practical procedure is to harden to a depth sufficient to give a satisfactory cutting edge, leaving the interior of the tool relatively soft.

**Quenching.**—High-speed steel usually is quenched in oil, or an air blast. If large tools are cooled too rapidly, there is danger of causing shrinkage cracks, and it may be desirable first to quench in a lead bath at 900–1000 deg. F., and to complete the quenching in oil.

**Straightening When Quenching.**—A tool that warps during quenching may be straightened within the few minutes immediately following quenching. The tool cannot be straightened later, as it becomes hard within a very short time after quenching.

**Tempering.**—After the hardened tool has been reduced to atmospheric temperature, it should be reheated to approximately 1000–1100 deg. F., held at that temperature for from 15 to 240 min. and cooled in air, in order to obtain maximum cutting efficiency and maximum transverse strength. This second heat treatment both increases the cutting qualities and the strength of the tool, and reduces brittleness. The maximum strength under impact, as measured by the torsion impact test, is obtained when the tool is given a secondary heat treatment at 900 deg. F.

**Heat Treatment in Small Shops.**—Where it is impracticable to install a modern type of heat treating furnace in a shop, tools should be purchased in the hardened condition, preferably in the form of bits. It is unwise to attempt to harden high-speed steel in the blacksmith's forge because of the uneven results obtained.

# PLANER WORK

**By Forrest E. Cardullo**

The planer is primarily a tool for generating flat surfaces, although by the use of special tools, fixtures and attachments, it may be used for forming surfaces, for planing curved surfaces, helixes, arcuate surfaces, and for doing various types of special work. Commercial planers are built in sizes to take work from 2 ft. wide by 2 ft. high by 5 ft. long, to work 16 ft. wide by 12 ft. high by 60 ft. long.

**FIELD OF THE PLANER.**—Work of the type usually performed on a planer, often may be done on a milling machine, shaper, slotter, or even on a lathe or boring mill. While each of these tools is preeminent in certain fields, in other fields they are competitive. The principal competitor of the planer is the milling machine, and it is desirable, therefore, to delimit the respective fields of these two tools.

The planer is preeminent in roughing large flat surfaces, especially when much finish is to be removed; in the accurate finishing of flat surfaces on medium-sized and larger work, especially if the material be cast iron; in the accurate finishing of such work as guides or slides when a number of pieces of identical cross-section may be placed in line and finished in one setting; in machining extremely hard materials.

The milling machine is preeminent in machining small surfaces, especially when the depth of cut is small, the material is soft, or extremely high cutting speeds may be used. The milling machine is preferable also when a large number of pieces are to be formed, or when the area to be machined is a small fraction of the area passed over by the tools, as is the case when raised bosses and strips are to be finished.

On ductile materials, the planer produces a more accurate but less smooth finish than the milling machine. On cast iron the planer produces a smoother, as well as a more accurate finish. Large steel castings usually are better planed than milled.

The planer is more versatile and adaptable than the milling machine for all types of work for which it is fitted. It is adapted to perform a number of operations in sequence on a single piece, or a few pieces. The set-up costs and tool costs are comparatively small. In the hands of a skilled operator it is extremely accurate. These properties obviously fit it for work on large pieces, for jobbing work, for tool room work, for work in shops building a general line of machinery, for emergency and repair work, and for work where accuracy is paramount, as in the building of machine tools. There is an overlapping field where either machine will produce satisfactory work at practically the same cost.

**POWER REQUIREMENTS OF PLANERS.**—Planers commonly are designed so that the power required at the moment of reversal is somewhat less than the maximum power delivered under a heavy cut. With the belts in proper condition, they will transmit about 4 Hp. per inch of width of cutting belt. The G. A. Gray Co., Cincinnati, recommends the following sizes of motors for planers. For light service, belt-driven: 24-in., 5 Hp.; 30-in., 7 1/2 Hp.; 36-in., 10 Hp. For medium service, belt-driven: 36-in., 15 Hp.; 42-in., 15 Hp.; 48-in. and over 20 Hp. For medium and heavy service, reversing motor drive: 36-in., 20 Hp.; 42-in., 25 Hp.; 48-in., 35 Hp.; 60-in. and 72-in., 50 Hp.; switch and frog planers, 50 Hp. The powers specified are ample for the simultaneous use of two tools. For more than two tools or for extra large planers, more power than is given above sometimes may be used to advantage, especially if the cutting speed be high. In such cases the planer builder should be consulted.

The power required to drive a planer depends on the rate of metal removal. When working to good advantage a planer tool cuts a rather thick chip, without much distortion, a condition favorable to economy of power. Planers usually are provided with from one to four tool-carrying heads, each head designed to withstand a tool pressure of from 5000 to 40,000 lb., depending on the size and type of planer. Such tool pressures can be obtained only under favorable circumstances. Usually the tool pressure is limited by the depth of cut, the feed which can be taken without damage to the tool or work, the extension of the tool, and the rigidity and strength of the work. It frequently is desirable to substitute a gang of three or four tools for a single heavy tool in order to avoid undue shock of entry, the breaking out of the work at the end of the cut, and the distortion of the work which would be produced by a heavy feed when taking a roughing cut. In general, the more tools that can be made to cut at once, the greater the economy of operation. Planers have been built in which 24 roughing tools and 16 finishing tools were simultaneously at work on eight pieces. Large heavy planers should have 75 Hp.

motors. For unusual service more power may be used to advantage. A 48-in. planer, roughing steel forging with four tools, may use 70 Hp. advantageously, and special multiple tooled planers, using a coolant at high speed, may require over 100 Hp.

**CUTTING AND RETURN SPEEDS.**—Cutting speed is dictated by the material being cut, and the kind of tool used. The return speed then is adjusted to give the greatest number of strokes in a given time. Belt-driven planers usually have only one cutting speed, from 30 to 45 ft. per min., and one return speed, from 80 to 100 ft. per min. As tool steels improve, the tendency is to increase the speed, but return speeds higher than 100 ft. per min. are not practical for belt-driven planers. When the speeds can be varied, as where planers are driven by a variable speed reversing motor, the usual cutting speeds are as follows:

| | |
|---|---|
| Cast iron (roughing) | 35 to 70 ft. per min. |
| " " (finishing) | 25 to 45 " " " |
| " " (chilled) | 2 to 6 " " " |
| Steel castings | 30 to 60 " " " |
| " forgings (soft) | 40 to 60 " " " |
| Steel forgings (hard alloys) | 12 to 30 ft. per min. |
| Bronzes | 40 to 60 " " " |
| Brass | 50 to 75 " " " |
| Aluminum alloys | 70 to 200 " " " |

All metals except cast iron are roughed and finished at the same speed. When large surfaces are to be finished accurately it is necessary to conserve the edge of the tool by using a wide feed and low cutting speed.

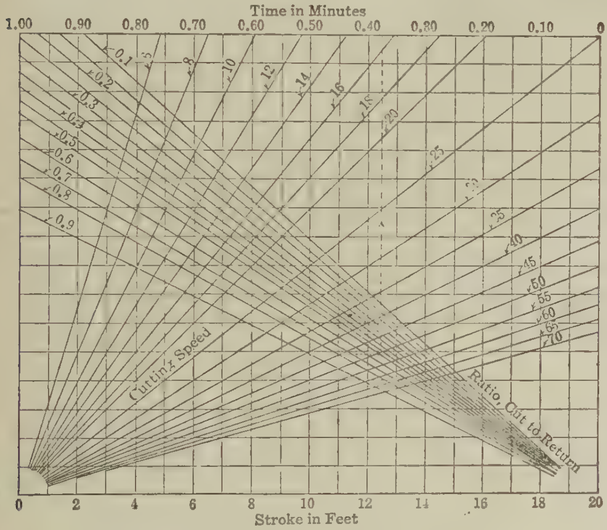

Fig. 1. Chart for Determining Cutting Speeds

**PLANER FEEDS.**—For rough planing cast iron, feeds range from $^1/_{16}$ in. to $^3/_8$ in. according to the depth of cut, power of the machine, and stiffness of the work and tools. For steel, the corresponding feeds are one-half those for cast iron. Down feed and undercut work require fine feeds. Frequently the feed must be reduced to prevent the cut from breaking out at the end. Cast iron finishing feeds range from $^1/_4$ in. to $1\,^1/_2$ in.

**TIME REQUIRED FOR PLANING.**—The number of round trips may be determined by dividing the width of the surface in inches by the feed in inches or fractions. From one to three extra round trips usually are necessary.

The time required for a round trip is the time required for the cut stroke plus the time required for the return stroke plus the time lost at the two reversals. The length of stroke usually is from 2 to 8 in. greater than the length of the work. To reduce this overrun, the feed should occur during the return stroke whenever this is possible. When gang tools are used, the overrun is increased by the distance between the cutting edges of the front and rear tools of the gang. The time lost during the two reversals varies from 0.015 to 0.020 min. with a first-class belt drive, to 0.03 min. with a good reversing motor, or 0.06 min. with a logy motor or one running at very high return speed.

Let $L$ = length of stroke, ft.; $B$ = backing or return speed, ft. per min.; $C$ = cutting speed, ft. per min.; $R$ = time lost in reversal per round trip, min.; $S$ = time per round trip, min.; $N$ = round trips per hr.; $F$ = feed, in.; $W$ = width of surface planed, in.; $T$ = time; $A = C/B$. Then

$$S = (L/B) + (L/C) + R \text{ minutes} = (L/C)\,(1 + A) + R \text{ minutes.}$$

$$N = 60/S = (60\,C) \div \{L(1 + A) + CR\} \text{ strokes per hour.}$$

$$T = WS/60F = W/NF \text{ hours.}$$

The chart, Fig. 1, gives values of $S$ which can be substituted in the above equations. To use the chart, first divide the cutting speed by the return speed, to obtain the value $A$.

From the intersection of the diagonal representing the cutting speed $C$, and the vertical representing the length of stroke $L$, proceed horizontally to the intersection of this horizontal with the diagonal representing $A$, thence vertically to read the value $S$ at the top of the chart. The chart assumes $R = 0.01$. The dotted line shows the method of finding $S$, which is 0.377 min., for a stroke of 11 ft., a cutting speed of 45 ft. per min., and a return speed of 90 ft., which gives a value of $A$ of 0.5. The time required to rough a piece of work requiring 11 ft. stroke, having a width of 18 in., and using a feed of $^1/_8$ in., and the above speeds, would be $T = (18 \times 0.377)/(60 \times {}^1/_8) = 0.904$ hr. To this, the time for setting up and removing work setting and adjusting tools, etc., must be added.

**DEVELOPMENTS IN PLANERS.**—The great majority of planers at present (1937) in service were built prior to the introduction of modern features of design. Helical or herringbone gearing, forced feed lubrication to vees and main bearings, oil clarifying systems, centralized lubrication of heads and gear boxes, power rapid traverse, improved feed mechanisms, which replace the old-fashioned friction feed, improved rail clamping mechanisms, and many other features have been introduced since 1920. These make machine operation and maintenance easier, increase rigidity and accuracy, reduce time for repairs, and increase the efficiency as a machine tool. Estimated savings due to such features vary from 20% to 40%, making it possible to replace three old-type planers with two modern machines, and at the same time obtain more accurate and satisfactory work.

**TOOLS AND FIXTURES.**—In many shops planers are not well equipped with tools and fixtures, and hence are able to operate at only a fraction of potential capacity. A study of the planer department often will result in increased efficiency when proper tools, fixtures, gages and other accessories are provided.

**High-speed Steel Tools** generally are used for roughing. High tungsten and tungsten-cobalt steels are preferred. High carbon steels often are used for fine finishing, but high tungsten steels with a high carbon content (special high temper) give practically as good results at much higher speeds. High carbon steels are preferred for planing chilled cast iron, being used at very low speeds. Blades of high-speed steel or of stellite sometimes are brazed to alloy steel shanks. High-speed steel bits also are used in carbon or alloy steel holders. A large variety of such bits and holders are used both for roughing and finishing and are successful and economical for a wide variety of work.

**The Superhard Cutting Tools** are not as satisfactory in planer service at the present time (1937) as high-speed steel. They lack the strength and toughness which normal planer service requires, and are apt to be chipped by careless handling of the machine. They are of use in planing dirty castings, in cleaning castings deficient in finish, where scale must be cut, and in planing work containing hard inclusions. While their usefulness at the present time is limited, it is entirely possible that their physical properties may be developed to the point where they will largely displace high-speed steel.

**A Set of Tools for General Work** includes right- and left-cut round-nose tools for roughing cast iron; the same for steel; a round-nose tool without side rake, for grooving; square-nose tools for second cuts and for "cutting down"; right- and left-cut side finishing tools; and gooseneck finishing tools. All of these tools may be obtained either in the forged type or the inserted bit type. The inserted bit tools usually are superior as finishing tools and for light cuts at high speeds, because of the superiority of their heat treatment. Forged tools usually are necessary when working in constricted openings, or close to shoulders or ledges.

**Other Useful Tools,** are chamfering tools, slotting tools, dovetail roughing tools, corner rounding tools, filleting tools, elling tools, self-relieving undercutting tools, and forming tools. Fig. 2 shows general purpose tools recommended by the G. A. Gray Co.

Unlike work done on machines intended for mass production, planer work seldom receives the attention of the production engineer. It usually is planned by the operator and his methods must be adapted to the fixtures and equipment available. Without the necessary tools and fixtures, even the most skilled and intelligent operator cannot work efficiently. Each planer should be supplied with two or more tools of each type that it is likely to require, so that it need not be shut down for forging or sharpening tools. As to fixtures and equipment, a variety of clamps should be provided, and also clamp bolts of various lengths, stop pins with adjustable screws, jacks, parallel blocks, washers, slot nuts, "file pieces" for holding down thin work, "pipe struts" for bracing high work, slot blocks for resetting parallel work, angle plates, squaring plates which can be doweled to the table for setting work when two surfaces are required to be square with each other, and special fixtures for holding work which must be done frequently. Since the planer can remove metal rapidly a good part of the floor to floor time on a planer job is set-up time. Adequate equipment for setting up work is essential to the efficient use of a planer. Such equipment cuts down set-up time, enables the operator to take heavier cuts, reduces the chance of accident, and produces more accurate work.

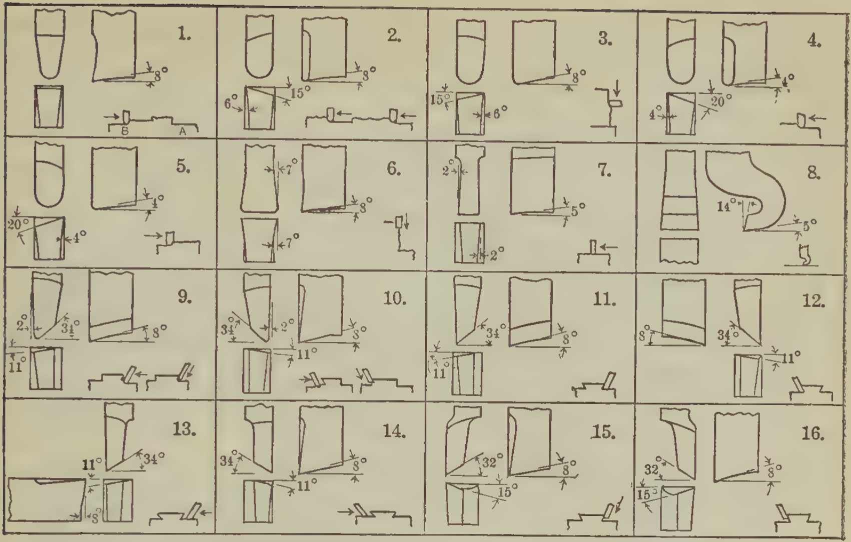

Fig. 2. Standard Shapes of Planer Tools. (See notes below)

In addition to the above equipment for each planer, the planer department should have an accurate and rigid four-sided cast iron square with diagonal bracing, a long and stiff straight edge with parallel sides, a sine bar, a large adjustable outside micrometer, a large adjustable inside micrometer, and two or three dial gages with universal mounting attachments. Dial gages may be used to advantage on the micrometers, and in gaging angles.

Finally, careful design of parts to be planed often will save much time. Lugs for supporting, bracing, stopping, measuring, or clamping pieces frequently are of advantage, later being planed or chipped off. Holes for lifting by chains, hooks, or clamps often are advantageous. Parts frequently are made in one piece at great expense, when a cheaper, more accurate and even more rigid design could be made in two pieces.

## Notes on Planer Tools. (See Fig. 2)

**Tool No. 1. Round-nose Roughing Tool for Cast Iron.**—Material, high-speed steel. For general-purpose, light roughing. Can be used in feeding from left to right or right to left. In planing two surfaces A and B at the same time, the tool is first fed from the right over surface A and then without changing setting, is fed from left over surface B. Tool has no side rake and maximum depth of cut is $^1/_2$ in.

**Tools No. 2 and No. 3. Right-cut and Left-cut Round-nose Roughing Tools for Cast Iron.**—Material, high-speed steel. Two of each of these tools required for a planer with two rail heads. Tool No. 2 feeds from right to left; tool No. 3 from left to right; also feeds down with the right-hand side head.

**Tools No. 4 and No. 5. Right-cut and Left-cut Round-nose Roughing Tools for Steel.**—Material, high-speed steel. Similar to tools Nos. 2 and 3, but ground for roughing cuts in steel. If used for cast iron, they will pull in and cause chatter. Tool No. 4 is used for planing from right to left and tool No. 5 from left to right, or for feeding down with right-hand side head. For removing a large amount of stock with these tools, use a deep cut, heavy feed, and slow speed.

**Tool No. 6. Square-nose Roughing Tool for Cast Iron.**—Material, high-speed steel. Used for roughing on flat surfaces where a sharp corner is to be made. Also can be used for straightening or heavy finishing cuts (depth of cut 0.004 to 0.005 in.). For lighter cuts and finer finishes use tool No. 8. Tool No. 6 can be made by brazing a high-speed steel tip to a machinery steel shank.

**Tool 7. Square-nose Finishing Tool for Cast Iron.**—Material, high carbon steel. A general purpose tool for straightening and finishing cuts. Advisable to have several different widths from $^3/_8$ to 1 in. Cutting edge of tool should be exactly parallel to surface of work. Feed should be coarse, almost the width of the tool.

**Tool No. 8. Gooseneck Finishing Tool for Cast Iron and Steel.**—Material, high carbon steel. Used to finish flat surfaces in any metal. Used with a very shallow cut and coarse feed. Cutting edge of tool should be finished with oilstone by hand, leaving a keen straight edge. Cutting edge should be exactly parallel to surface of work.

**Tools No. 9 and No. 10. Right-hand and Left-hand Dovetailing End Cutting Roughing Tools for Cast Iron.**—Material, high-speed steel. Cutting edge of tool at the end. Corner rounded off to avoid breakdown in taking roughing cut. Tool No. 9 is fed downward or from right to left. Tool No. 10 is fed from left to right and downward. Tools Nos. 9 and 10 should be followed by tools Nos. 11 and 12 to leave a sharp corner.

**Tools No. 11 and No. 12. Right-hand and Left-hand Dovetailing End Cutting Roughing Tools for Cast Iron.** Material, high-speed steel. These tools are similar to tools Nos. 9 and 10, and are intended to clean out corners after most of the metal has been removed by the other tools. Not as well suited for general dovetail roughing as tools Nos. 9 and 10, because the sharp corner breaks down. Tool No. 11 feeds downward or from right to left; tool No. 12 feeds in the opposite direction and downward.

**Tools No. 13 and No. 14. Right-hand and Left-hand Dovetail End Cutting Finishing Tools for Cast Iron.**—Material, high carbon steel. For finishing flat surfaces with cutting edge at end of tool. Used after roughing cuts with tools Nos. 9, 10, 11, and 12. Tool No. 13 feeds from right to left and tool No. 14 from left to right.

**Tools No. 15 and No. 16. Right-hand and Left-hand Dovetail-side Cutting Finishing Tools for Cast-iron.**—Material, high carbon steel. Used for finishing angular surface of dovetail. Tool No. 15 feeds downward with cross feed, taking very light cut. Tool No. 16 feeds downward with cross feed and light cut.

**General Notes on All Tools.**—For fair finish, set roughing tool to final dimensions. The finishing tool merely removes the high spots. For accurate finish, leave work 0.006 in. oversize when roughing, followed by straightening cut leaving 0.001 in. to be removed by finishing cut. Tools should be made from the following sizes of bar. From 24-in. to 36-in. standard planers, 1 × 1 1/2 in. bar; 36-in. to 48-in. maximum service planers, 1 1/8 × 1 3/4 in. bar; 56-in. to 72-in. maximum service planers, 1 1/4 × 2-in. bar.

## Planer Drives

Small planers usually are driven by shifting belts, the "cut" belt being crossed and the "return" belt open. Such belts must be kept pliable, but not sticky. They are stretched somewhat more tightly than is good practice in other types of machinery, in order to get a belt narrow enough to shift readily, and still deliver the requisite power. Belt-driven planers usually operate at about 33 ft. per min. cutting speed and 90 ft. per min. return speed and deliver about 4 Hp. per inch of width of cutting belt.

The maximum satisfactory belt width is 4 in. Belt drives usually are used for very small planers and, when direct current is not available, for reversing motor drive. Belt-driven planers reverse more quickly than reversing motor-driven planers, although modern (1937) reversing motors are much more efficient in this respect than motors built a few years previously. The belt drive gives only one cutting speed, unless provided with means for varying the speed of the overhead cutting belt pulley independently of the speed of the overhead return belt pulley. In such cases, cutting speeds ranging from 25 to 60 ft. per min. usually are provided.

For heavy work, planers 36 in. wide and over usually are operated by 230-volt, reversing, variable-speed, direct-current motors with field control. Such motors are made, having speeds ranging from 250 to 1000 r.p.m., from 200 to 1200 r.p.m., and from 150 to 900 r.p.m. Planers usually are so geared that ten revolutions of the motor shaft moves the table one foot or more. Switch planers are so geared that 13 to 15 revolutions of the motor shaft moves the table one foot. The field control should be so arranged that the entire speed range is available for both cut and return speeds. Table speeds of 25 to 100 ft. per min. formerly were standard. Higher speeds are coming into favor, and maximum table speeds of 120 to 200 ft. per min. are not unusual. Variable-voltage drives consisting of a special motor-generator set for each planer, energizing a variable-voltage motor, are used when extreme speed ranges are required. Such drives, while expensive, give motor speeds ranging from 40 to 1200 r.p.m., and make possible table speeds ranging from 4 to 120 ft. per min., or with special gear ratios, speeds up to 300 ft. per min.

Hydraulically-driven planers lose less time in reversal than reversing-motor or belt-driven planers. For short strokes and light and medium work, such planers often are found to be satisfactory. However, the hydraulic cylinder located immediately below the table becomes very hot in service, causing unequal expansion of the planer members, and making precision work difficult. Hydraulic planers are not adapted for heavy duty work or long stroke work because of their lack of power and their tendency to chatter, due to the compressibility of the liquid.

In Europe, some planers have cutting speeds of 100 to 250 ft. per min. There are no tools available to operate at such speeds and give reasonable tool life, except on aluminum, similar alloys, and some non-metallic materials.

# MILLING MACHINE PRACTICE

By Hans Ernst and Mario Martellotti

## 1. ANALYSIS OF THE PROCESS OF MILLING

**FUNDAMENTAL CONCEPT.**—The milling process may be considered as a method of metal removal in which the portion of the work piece that is to be removed is projected into the space dominated by a rotating body carrying one or more individual cutting teeth. The profile of the finished surface produced on the work piece, therefore, is determined by the intersection of a plane, perpendicular to the motion of the work piece, and the outline of the body of revolution generated by the rotating cutter.

Two main classes of milling operations are:

1. **Face Milling,** in which the finished surface mainly is parallel to the face of the cutter.
2. **Peripheral Milling** (including slab and form milling), in which the finished surface mainly is parallel to the periphery of the cutter.

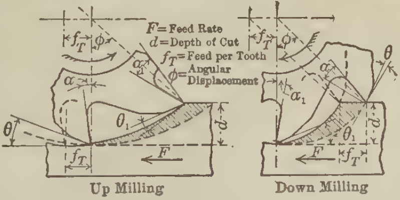
**CHARACTERISTIC FORM OF MILLING CHIP.**—Because of the limited period of engagement of each tooth with the work piece, the removal of metal in milling is accomplished by the separation of small individual chips. The rotary motion of the cutter and the translatory motion of the work piece combine to produce a chip whose cross-section varies from instant to instant as the direction of motion of a tooth changes with respect to direction of motion of the work piece. Chip thickness is a maximum at the instant that these motions are perpendicular to each other, and substantially zero when they are parallel.

**SURFACE GENERATED IN MILLING.**—In peripheral milling, two distinct methods are used:

**Up-milling.**—The work piece advances toward the cutter from the side where the teeth are moving upward. The cutter rotates against the direction of the feed. The chip thickness is a minimum at the beginning of the cut and a maximum at the end.

**Down-milling.**—The work piece advances toward the cutter from the side where the teeth are moving downward. The cutter rotates in the same direction as the feed. The chip thickness is a maximum at the beginning of the cut, and a minimum at the end.

Fig. 1 compares the shape of milling chips produced by these two methods, the difference in shape being exaggerated by the use of a large feed per tooth. In both methods the path of a tooth through the work material is a curtate trochoid. Its actual shape will vary with changes in rate of feed, diameter of cutter, depth of cut, and cutting speed. Fig. 1 shows that the actual rake and clearance angles change continually as the tooth forms a chip. In up-milling, the actual clearance angle $\theta$ is greatest at the beginning of the tooth contact with the work, decreasing to a minimum value of $\theta_1$ when the tooth leaves the work. The actual rake angle, however, has a minimum value $\alpha$ at the beginning of the cut, increasing to maximum value $\alpha_1$ at the point of leaving the work. In down-milling, the actual clearance angle $\theta$ is least at the beginning of the cut and greatest, $\theta_1$, at the end; the actual rake angle $\alpha$ is greatest at the beginning of the cut, and least, $\alpha_1$, at the end.



Up Milling    Down Milling

FIG. 1

In this respect, milling differs radically from other machining processes, as turning, planing, etc., in which clearance and rake angles remain constant throughout the cut.

**CHIP FORMATION.**—Up-milling and down-milling produce surfaces of entirely different character, the reason lying in the nature of the process of chip formation. When a cutting tool engages a work piece, the material immediately ahead of the cutting edge is at first compressed and escapes by flowing in a direction parallel to the face of the tool. See Fig. 2. As the tool continues to advance, however, escape in this direction becomes increasingly difficult; the pressure on the tool rises; the stress in the material further ahead of the tool increases, finally reaching a value great enough to cause rupture or flow in a plane roughly perpendicular to the face of the tool. If the material is relatively brittle, or the thickness of chip is great, a definite rupture will occur in this plane. The entire portion of severed material then will move out of the path of the advancing tool, and permit the engagement of a fresh portion. The chip will not be a continuous ribbon, but a series of individual segments more or less closely joined. This type of chip is known as a segmental chip.

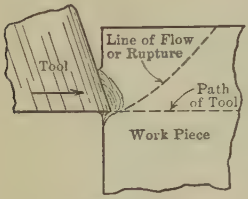


Fig. 2

If the material is relatively ductile, definite successive ruptures will not take place; instead, the material ahead of the tool will yield by plastic flow over a broad region. As this material (*A*, Fig. 3) is forced out of the path of the advancing tool, it separates from the initially compressed portion *B*, which is held by frictional contact with the tool face. The body of the chip passes off as a substantially solid ribbon, with flow lines perpendicular to the tool face. The wedge-shaped portion *B*, with flow lines parallel to the tool face, remains to form the so-called *built-up edge.* This type of chip generally is known as a flow-type chip. The built-up edge is added to continuously by material compressed at point *C*, but is periodically reduced by fragments, as *D* and *E*, torn off both the chip and work piece, respectively.

Roughness of a machined surface is due solely to the presence of fragments such as *E*; consequently, for good finish, their magnitude should be kept to a minimum by so arranging conditions that the stable size of the built-up edge itself is a minimum. Such arrangements include: 1. Decrease in chip thickness; 2. Increase in rake angle; 3. Increase in tool sharpness; 4. Increase of cutting speed; 5. Use of cutting fluid; 6. Use of work material of lower ductility. See H. Ernst and M. Martellotti, Metal Cutting, *Mech. Engg.*, Aug., 1935.

B
A
C
E
Work-Piece

Fig. 3

In up-milling, the portion of the finished surface which is produced by a tooth is formed at the beginning of its contact with the work piece, when the chip thickness is extremely small. Hence, the built-up edge itself is very small, and the resultant surface is smooth and shiny. In down-milling an element of the finished surface is produced at the end of the tooth engagement with the work. With a ductile material such as a low-carbon steel, where the built-up edge is large, the latter persists to the extreme end of the chip; thus the escape of fragments likewise persists, and produces a somewhat torn finish similar to that obtained by planing or shaping. With a less ductile material, such as a high carbon steel, the built-up edge is smaller; hence, the difference in finish between up-and-down methods of milling is less marked. (See discussion of paper by O. W. Boston and C. E. Kraus, The Elements of Milling, *Trans.* A.S.M.E., RP 54–4, 1932, p. 96.)

## 2. MILLING CUTTERS

### Forms of Milling Cutters

The following classification and nomenclature relative to milling cutters are based on the standards approved by the American Standards Association, and adopted by the leading manufacturers. See A.S.A. *Bulletin*, 5C–1930. Tables 1 to 9 show principal dimensions of the most commonly used types of milling cutters, as approved by the American Standards Association. These dimensions have been adopted as standard by the cutter manufacturers.

**CLASSIFICATION BASED ON RELIEF OF TEETH.—1. Profile Cutters.**—All forms of cutters which are sharpened by grinding on the periphery of the teeth, the clearance (or relief) being obtained by grinding a narrow land back of the cutting edge. Where the cutting edges are of curved or irregular shape, they are designated as Shaped Profile Cutters.

**2. Formed Cutters.**—All cutters where the eccentric relief back of the cutting edge is of the same contour as the cutting edge itself. These cutters are sharpened by grinding the face of the teeth.

**CLASSIFICATION BASED ON METHOD OF MOUNTING.—1. Arbor Cutters.**—A cutter with hole for mounting on arbor.

**2. Shank Cutters** have either a straight or taper shank integral with the cutter.

**3. Facing Cutters** are designed to be attached directly to spindle end or to stub arbor.

**GENERAL TYPES OF CUTTERS.**—The commonly used types of cutters, and the work to which they are adapted are:

**The Plain Milling Cutter** is a cylinder with teeth on the circumferential surface only. It is used to produce a flat surface parallel to the axis of the cutter. Plain milling cutters are made in a wide variety of diameters and widths, for the various requirements of slab milling. They generally have helical teeth. The helical form enables each tooth to take a cut gradually, thus reducing shock and minimizing tendency to chatter. Cutters with a helix angle of 25 to 45 deg. commonly, but incorrectly, are termed *spiral mills*; if helix angle is more than 45 deg. the cutter generally is known as a *helical mill.*

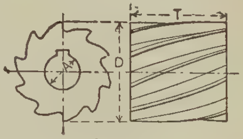

Fig. 4

The helical mill, which may be either of the shank or hole type, is free cutting and particularly desirable for light cuts on soft steel or brass. It can run at high speeds and, therefore, produces a good finish. It can be used to advantage for profiling work such as cam milling, and for milling intermittent surfaces. The shank type, with pilot end, commonly is used for elongating slots. For general slab milling, the helical mill is not as efficient as the common "spiral" mill.

**Table 1.—Dimensions of Heavy Duty Plain Milling Cutters**

See Fig. 4

| Cutter Diam., *D*, in. | | | Diam. of Hole, *A*, in. | | Nominal Widths of Face, *T*, in. |

| Minimum | 2.000 | 2.500 | 3.000 | 4.000 | 6.000 | 12.000 |

**The Side Milling Cutter** is a plain milling cutter of cylindrical form with teeth on the circumferential surface and on both sides. The side teeth extend a portion of the distance from the circumference to the axis. Half side and interlocking side milling cutters also are made. Side milling cutters are used in a large variety of work. Two or more of them often are placed on the same arbor with a space between them, they then being known as straddle mills.

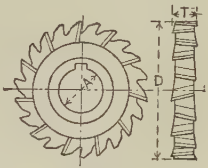

Fig. 5

**Straddle Mills** are used to advantage where the work is to be milled on two parallel sides; *e.g.*, bolt heads, tongues, etc.

**Table 2.—Dimensions of Stagger Tooth Milling Cutters**

**Interlocking Cutters** are used to mill slots to a standard width. They are maintained at a constant width by thin shims or collars between the inner hubs.

**Staggered Tooth Milling Cutters** are cylindrical cutters with the cutting teeth on the circumferential surface only. Alternate teeth are of opposite helix angle. See Fig. 5. The side teeth extending from the circumference a short distance towards the axis are for chip clearance only. They are not ground for cutting purposes. This type of cutter is used to obtain exact width of slots and is the most efficient type for milling slots where depth exceeds width. Because of the alternate right- and left-hand helix angle of the teeth, with considerable undercut, these cutters can remove large amounts of metal without vibration or chatter. The free cutting action makes possible an increased feed and speed, without detriment to the production of smooth, accurate work.

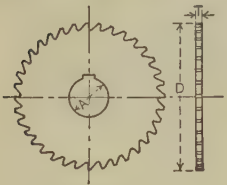

Fig. 6

**Metal Slitting Saws** are plain milling cutters with sides relieved or "dished" to give side clearance. They generally are made 3/16 in. thick or less, and usually have more teeth for a given diameter than a plain milling cutter. They are used to cut off work, or to mill very narrow slots. Slitting saws also are made with side teeth similar to side milling cutters, and with staggered teeth, similar to staggered tooth milling cutters. The metal slitting saw with staggered teeth usually is made 3/8 to 3/16 in. thick, and is used for heavy sawing in steel.

**Table 3.—Dimensions of Metal Slitting Saws**

**Angle Milling Cutters** are made both **single angle** and **double angle**, with teeth on the conical surfaces. See Figs. 7 and 8. Single angle cutters are made both with and without teeth on one or both of the flat sides. Angle cutters are used for various fluting operations, or for milling the edge of a piece to a given angle.

* Included angle 45 or 60 deg. ± 10 min. † Included angle, 45, 60 or 90 deg. ± 10 min.

**End Mills** are cutters with teeth on the circumferential surface and on one end. See Fig. 9. The teeth may be either parallel to the axis of rotation or helical, and either right or left hand. End mills of moderate angle commonly are called spiral end mills. End mills are made of five general types, *viz.*, Solid end mill; two-lip end mill or slotting mill; shell end mill; hollow mill; helical end mill.

**Solid End Mills** are used for light milling operations, as the milling of slots, profiling, and facing narrow surfaces. The teeth are integral with the shank, which may be either straight or tapered.

**Two-lip End Mills** comprise a shank cutter with two cutting teeth on the circumferential surface, and end teeth cut to the center. Flutes are either straight or helical. The cutter can be sunk into the material and then fed longitudinally. A depth of cut equal to one-half the diameter of the mill usually can be taken from the solid stock.

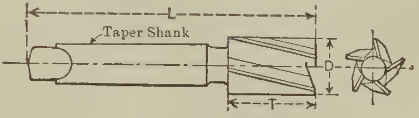

FIG. 9

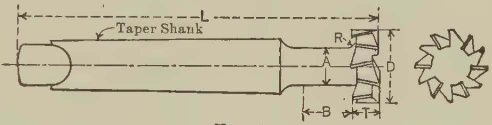

FIG. 10

**Shell End Mill.**—Teeth are cut on the circumferential surface and on one end. See Fig. 11. The tooth end is recessed to receive a nut or screw head for holding the cutter on the stub arbor. It usually is driven from the key slot across the back face. The teeth may be parallel to the axis of rotation, or helical, and either right or left hand. This type of milling cutter should be used in preference to the solid end mill whenever possible, because it is cheaper to replace when worn out or broken.

**Hollow Mill.**—A cutter of tubular construction with teeth on one end, and having an internal clearance. The internal clearance sometimes is obtained by a plain tapered hole with back taper and sometimes by internal cleared flutes. The hollow mill generally is used for producing bosses or cylindrical projections from solid bodies.

**T-slot Cutter.**—A shank cutter designed for milling T-slots. See Fig. 10. The teeth are on the circumferential surface and both sides. In making a T-slot, a groove first is cut with an ordinary side milling cutter or a two-lipped end mill. The wide groove at the bottom then is cut with the T-slot cutter.

* Neck diameters as given are to be used with American Standard T-slots.

**The Woodruff Key Seat Cutter** is made in the **shank** and **arbor** type. The shank type generally has teeth on the circumferential surface only, with the sides slightly relieved for clearance. The arbor type generally is used in sizes larger than 2 in. diameter. These cutters also are made with staggered teeth. They are made with teeth on both sides which are ground for clearance only and not for cutting. Both types of cutters are used for the specific purpose of milling semi-cylindrical keyways in shafts, to permit the use of Woodruff keys.

**Formed Cutters** usually are of curved irregular outline. They are sharpened by grinding the faces of the teeth. So long as the face of a tooth is maintained in its original plane with respect to the axis of rotation, the contour of the tooth will remain unchanged. Formed cutters are used for duplicate interchangeable work over and over again until they have been ground to a point where the teeth are too slender to stand the strain of the work.

In the formed cutter class are included such cutters as: *Gear Cutters, Multiple Gear Cutters, Sprocket Cutters, Convex Cutters, Concave Cutters, Corner Rounding Cutters, Spline Cutters, Thread Milling* and *Hobbing Cutters*, etc.

**A Fly Cutter** consists of a single cutter similar in shape to a planer tool, held and rotated by an arbor. As it has but a single cutting edge, it is used but rarely outside of the experimental room or tool room. The fly cutter can be formed exactly to any desired shape. Its field is operations that would not bear the expense of a special form cutter.

**Inserted-tooth Facing Cutter.**—This type of cutter, generally known as a **Face Mill,** is a cylindrical body with slots on its periphery. Blades of various cutting materials, as high-speed steel, Stellite, or blades tipped with cemented carbide, are inserted in the slots. The teeth of the facing cutter are ground to cut both on the circumferential surface and on the side, as in the **Side Mill.** These cutters are adapted to be attached directly to the end of the spindle, or to a stub arbor.

**Face Mills** are used to face large surfaces, and are very efficient in the removal of metal.

*The Heavy Duty Face Mill* is made with a stronger body, and thicker and fewer blades than the light duty type. It generally is used for roughing cuts.

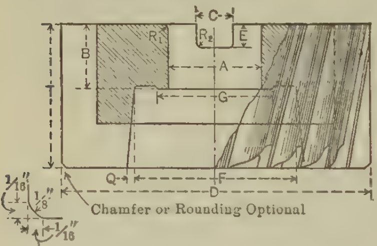

Fig. 11

*The Light Duty Face Mill* has a lighter body and a larger number of teeth than the heavy duty type, and is used mostly for finishing cuts. Face mills with high-speed steel inserted blades, tipped with cemented carbide, or with stellite blades, are used almost exclusively for milling cast iron and non-ferrous materials. They have more teeth and usually are run from two to three times faster than face mills with high-speed steel blades.

The inserted tooth milling cutter is most economical and useful when cutters of large dimensions are required, although they are obtainable also in diameters as low as 3 in. Almost all types of milling cutters may be made with inserted teeth. Their use is becom-

ing more and more common, even in small diameter cutters, particularly with cemented carbides.

**DIRECTION OF ROTATION.**—A cutter is **right-hand** if it rotates counter-clockwise, and **left-hand** if it rotates clockwise, when viewed from the front end as mounted on the spindle.

**MATERIAL FOR MILLING CUTTERS.**—Four classes of materials commonly used for milling cutters are: Carbon steel; high-speed steel; Stellite; cemented carbide.

**High-speed Steel Cutters** predominate, although carbon steel is used to some extent for screw slotting and slitting cutters and other light duty work. Practically all heavy-duty plain milling cutters are made of high-speed steel. For most classes of work, high-speed steel cutters can be run from 2 to 2 1/2 times as fast as carbon steel cutters.

**Stellite** is employed generally in the form of inserted blades in face mills for use on cast iron. The life of Stellite cutters is generally longer than that of similar high-speed steel cutters and the permissible cutting speed higher.

**Cemented Carbide.**—Inserted-blade face milling cutters, tipped with various types of cemented carbides, are (1937) replacing other types of cutters for use on cast iron. Cutting speeds normally employed are from 2 to 3 times as high as those used with high-speed steel cutters, and a considerable improvement in finish usually is obtained. Because of the extreme hardness of these carbides, a smaller allowance for finish is permissible, thus further increasing production and reducing costs.

**NUMBER OF TEETH.**—No standard rule exists for the number of teeth in milling cutters. Modern cutters (1937) generally are of the " coarse tooth " type, the spacing offered commercially by cutter manufacturers having been found satisfactory for most purposes.

The coarse tooth cutter provides a great chip space between successive teeth, which permits a free flow of the chip and prevents clogging of the teeth. The efficiency of the modern coarse tooth cutter is considerably higher than that of the old style fine tooth cutter. See A. L. DeLeeuw, Milling Cutters and their Efficiency, *Trans.* A.S.M.E., xxxiii, p. 245, 1911, also J. A. Hall and B. P. Graves, Effect of Variation in Design of Milling Cutters on Power Requirements and Capacity, *Trans.* A.S.M.E., lxv, p. 165, 1923.

## 3. USE OF MILLING CUTTERS

**CUTTING SPEED.**—Because of the countless variations in conditions encountered in milling practice, fixed rules for cutting speeds are impossible. The most effective speeds are governed by the structure and hardness of the part to be machined, the amount of metal to be removed, the type of cutting material, etc. In general, cutting speed is selected to give the best compromise between maximum production and maximum life of the cutter. The values given in Table 10 are conservative and represent average practice on production jobs.

The cutting speed for finishing milling often is 40% to 80% higher than the roughing speed.

**FEED RATE.**—The rate of production in milling depends directly on the rate at which the work passes the cutter, but the selection of the proper feed rate for milling a given work piece involves several factors, among them being the limitations of machine, cutter, work piece, and fixture; the finish desired, etc.

Estimates of feed rates usually are based on the assumption of a certain value for the feed per tooth. This is multiplied by the number of tooth passages per minute, as determined from the desired cutting speed and tooth spacing, to obtain the feed rate in inches per minute. This then must be checked with the above limitations.

In practice the feed per tooth is made as large as possible, consistent with these limitations and the permissible tooth load. Table 11 gives average values of permissible feed per tooth for various combinations of cutting material and work material. These values must be reduced when using cutters, or work, of a relatively fragile nature.

**DIAMETER OF CUTTER** usually is determined by the limitations of the work piece, either in regard to the size of the surface to be milled, or interference with adjacent

Table 11.—Permissible Feed per Tooth of Milling Cutters

* B = Approximate Brinell Hardness Number. † R = Rockwell B Scale.

portions of work or fixture. In the case of cutters of small diameters, the limitation frequently is the size of the arbor required to support it properly.

**CLEARANCE ANGLE (Relief).**—The sole function of clearance or relief of the flank surface, is to prevent undue interference between it and the surface of the work. Where the direction of the motion of the flank surface, relative to the work, is parallel to the finished surface (as in the case of a shaper tool or planer tool) the clearance angle need be only sufficient to allow for the slight expansion of fragments of the built-up edge which escape with the work piece as the latter passes under the tool. Any clearance greater than the minimum amount required increases the likelihood of chatter, and reduces the life of the tool.

In the case of a peripheral cutting edge of a milling cutter, the direction of motion of the tooth relative to the direction of the feed varies with the position of the tooth in its arc of contact with the work piece. In up-milling, the motion of the tooth is parallel to the feed at the instant of engagement, and inclined thereto when leaving the work. Throughout its contact with the work piece, there is an increasing component of the feed tending to cause interference with the flank surface, and thus an additional clearance must be provided.

The additional clearance angle necessitated by the feed component depends on the diameter of the cutter, $D$, the feed per revolution, $F_r$, and the depth of cut $d$. Its value may be computed from

$$\theta = \frac{180}{\pi}\left\{\frac{2\,F_r}{D}\sqrt{\frac{\pi d(D-d)}{\pi(\pi D + F_r)^2 - F_r\,d}}\right\} \quad . \quad . \quad . \quad . \quad . \quad . \quad [1]$$

where $\theta$ is given in degrees, and $D$, $F_r$ and $d$ are in inches.

The minimum permissible clearance angle also is affected by the width of the flank (or *land*) back of the cutting edge. This should be kept to a small value, usually not greater than $^1/_{32}$ in., in order that the true clearance at the cutting edge may be as small as possible. As shown in Fig. 14, a secondary clearance angle beyond this land usually is provided to avoid interference, and to reduce the amount of material which must be removed when regrinding the cutter. The values of clearance angles commonly used range from 3 to 5 deg. for steel, to about 10 deg. for aluminum.

**RAKE ANGLE** of a milling cutter (see Fig. 14) is defined as the angle by which the face of the tooth is displaced back of the radial line drawn from the center of rotation to the cutting edge. Efficiency of metal removal increases with increase in the rake angle. Consequently, the latter should be as large as possible consistent with strength. In practice, rake angles ranging from 10 to 15 deg. commonly are used.

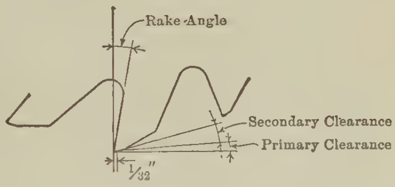

FIG. 14

**CUTTING FLUIDS,** consisting generally of oils or emulsions, are used to protect the cutter, and improve the quality of the finish. They have three main functions:

**1. Cooling.**—A large amount of heat is generated in metal cutting, particularly with strong ductile materials such as steel, where a flow type chip is produced. Heating of the tool point causes a reduction in resistance to abrasion, thus hastening dullness or wear. Heating of the material also may impair the finish by increasing the size of the built-up edge. For efficient cooling, a cutting fluid should have a high specific heat coefficient.

**2. Lubrication.**—By lubrication of the tool face, resistance to chip flow is reduced, thus reducing the size of the built-up edge and improving the finish, and also reducing the total force on the tool. This will increase the tool life. For efficient lubrication, the cutting fluid should have a low surface tension with respect to the tool and work material, and a high film strength to withstand the high specific pressures encountered.

**3. Flushing of Chips.**—The cutting fluid should be supplied in sufficient quantities to flush the chips away from the cutter and work, thus reducing the likelihood of marring the finished surface.

**Composition.**—Emulsions consisting of soluble oils and water are used widely in milling, because of their effectiveness as coolants, and the ease with which they may be used in large quantities for flushing away the chips. For milling of tough alloy steel forgings, however, heavy cutting oils often are used, the composition varying with the nature of the work and the finish required. Special compounded oils, such as sulphurized oils or chlorinated oils, are being used to an increasing extent because of their value as extreme pressure lubricants.

**COMPARISON OF UP-MILLING AND DOWN-MILLING.**—At various times during the past 50 years down-milling (or milling with the feed) has been advocated for particular classes of work, in view of certain advantages inherent in this method. In recent years this method has been used with special types of feed systems, designed to prevent an overrunning of the milling machine table due to the action of the cutter on the work.

When using thin metal slitting cutters the likelihood of producing crooked slots is less when cutting down than when cutting up. In milling the flutes in twist drills, and other similar operations, a longer tool life and more desirable finish has been obtained when milling down, and the holding of the work piece during the milling operation is greatly simplified. On the other hand, when milling a low carbon steel or other ductile material, the finish is much inferior than with the conventional up-milling method. The greatest practical objection to the down-milling method for heavy milling work is the danger of a serious accident if the work piece or fixture should be insecurely fastened to the table.

From the standpoint of power required there is little to choose between the two methods of milling. Careful tests have shown in most cases that there is very little difference between the power actually used by the cutter when removing chips either by up-milling or down-milling.

**POWER REQUIRED FOR MILLING** is a function of many factors, including the cutting speed, the feed, the material being cut, the rake angle, the sharpness of the cutter, the depth of cut, the smoothness of the face of the teeth, the type of cutting fluid used, etc.

An empirical formula which can be used for a rough determination of the power required in milling is

$$\text{Hp.} = KFWD \quad \ldots\ldots\ldots\ldots \quad [2]$$

where Hp. = horsepower actually used in cutting; $F$ = feed rate, in. per min.; $W$ = width of cut, in.; $D$ = depth of cut, in.; $K$ = a constant which is different for different materials; values are given in Table 12.

In order to obtain the total actual power required to perform a milling operation in any given type of milling machine, it is necessary to add to the result of calculation by formula [2], the idle power required to drive the machine. Idle power varies in relation to the type of milling machine used. However, it generally is found that the idle power is approximately constant within the range of loads encountered in ordinary milling machine operation. For more exact determination of the power involved in milling, the following formula can be used:

$$\text{Hp.} = CWf^{a}D^{b} \quad \ldots\ldots\ldots\ldots \quad [3]$$

where Hp. = actual horsepower used in cutting; $W$ = depth of cut, in.; $f$ = feed per tooth, in.; $D$ = depth of cut, in.; $C$ = a constant.

Constants $C$ and exponents $a$ and $b$ are determined by experiment. They vary with the material being cut, the type of cutter used, the nature of the cut and with up-milling or down-milling. O. W. Boston and C. E. Kraus (*Trans.* A.S.M.E., RP–56–1, 1934) discuss the results of tests with a single point tool and of a great number of commercial tests on milling. They present values of $C$, $a$ and $b$ for three steels, *viz.* S.A.E. 1020, S.A.E. 1112 and S.A.E. 3250, and also a free-cutting leaded brass of analysis Cu, 0.62; Zn, 0.34; Pb, 0.03. Cuts were made both in a groove and on a land, with cutters whose helix angles ranged from 0 to 40 deg., and whose rake angles ranged from 0 to 15 deg. The range of the values of the exponents and constants was as given in Table 13.

The following summarizes the variation of the exponents $a$ and $b$ and the constant $C$.

With down-milling, $C$ in most cases is lower than with up-milling. In general, $C$ for a 25-deg. rake angle is about 55% of its value for a 0-deg. rake angle, and varies but little for the greater

angles of rake. The value of $C$ remains practically constant with all helix or side rake angles up to 30 deg., with a sharp increase at 40 deg., due probably to excessive metallic distortion of the chip.

The feed exponent $a$ remains practically constant as the rake angle increases, although a slight decrease is apparent for land cutting. It also remains practically constant as the helix increases, except that for extreme values of helix in groove cutting the value of $a$ is high.

The depth exponent $d$ decreases slightly with high rake angles, and increases slightly for high helix angles when milling in a groove. The exponent remains practically constant when milling is on a land.

**TYPICAL MILLING JOBS. SPEEDS. FEEDS.**—The following are representative examples of good commercial practice:

**Automotive Practice.**—1. Rough mill cylinder blocks, top and bottom, manifold, bearing cap slots, and valve cover pads, using Stellite tools: Cutting speed, 110 ft. per min.; feed, 10.5 in. per min.; depth of cut, $1/8$ in.; production, 13.6 pieces per hr.; pieces per grind, 200.

2. Mill clutch housing on cylinder blocks, using cemented carbide tools: Cutting speed, 250 ft. per min.; feed, 12 $1/2$ in. per min.; depth of cut, $1/32$ in.; production, 60 pieces per hr.; pieces per grind, 6720.

3. Finish-mill rear end of cylinder blocks, using cemented carbide tools: Cutting speed 250 ft. per min.; feed, 16 in. per min.; depth of cut, 0.015 in.; production, 44 pieces per hr.; pieces per grind, 3168.

4. Mill mounting pads of master cylinder body, using Stellite cutters: Cutting speed, 140 ft. per min.; feed, 11 $1/4$ in. per min.; depth of cut, $1/8$ in.; production, 130 pieces per hr.

5. Mill bosses on shock absorber body, using Stellite cutters: Cutting speed, 128 ft. per min.; feed, 25 in. per min.; depth of cut, $3/16$ in.

Table 14 gives data concerning the milling operations on a 12-cylinder automobile motor block.

**General Practice.**—1. Bottle mold halves; mill parting faces and tongue, using tungsten carbide and high-speed steel cutters: Material, cast iron; cutting speed, tungsten carbide cutters, 170 ft. per min.; high-speed steel cutters, 53 ft. per min.; feed rate, tungsten carbide cutters, 9 $7/8$ in. per min.; high-speed steel cutters, 3 $5/8$ in.; depth of cut, $1/16$ in.

2. Roller-spider; mill three cams using high-speed form cutter: Material, steel forging; cutting speed, 78 ft. per min.; feed variable, average, 5 $1/2$ in. per min.; depth of cut, $1/16$ in.; time per piece, 1.22 min.; production, 42 pieces per hour.

3. Transmission case; mill face, using high-speed steel cutters: Material, cast iron; cutting speed, 60 ft. per min.; feed, 5 in. per min.; production, 8 pieces per hr.

4. Compressor cylinder; Material, S.A.E. 1112 steel; high-speed steel slotting cutter: cutting speed, 64 ft. per min.; feed, 5 $3/8$ in. per min.; depth of cut, 0.025 in.; production, 229 pieces per hour.

5. Master cylinder body; mill mounting pads, using Stellite face mill cutter: Material, cast iron; cutting speed, 140 ft. per min.; table feed, 11 $1/4$ in. per min.; production, 130 pieces per hour.

6. Block plunger feed trip; mill slot and angle using a gang of high-speed steel cutters: Material, S.A.E. 1112 steel; cutting speed, 65 ft. per min.; feed rate, 2.4 in. per min.; depth of cut, 1 $1/2$ in.; production, 12 pieces per hr.

7. Fork; mill inside and outside of fork; mill radius and end, form-mill other radius and end. Material, steel casting; 1st and 2nd operation: Use gang of four high-speed steel cutters; cutting speed, 55 ft. per min.; feed rate, 5 $3/8$ in. per min.; depth of cut, $1/8$ in. 3rd operation: Use high-speed steel form cutter; cutting speed, 50 ft. per min.; feed rate, 3 in. per min.; depth of cut, $1/8$ in.; production, 6 pieces per hr.

8. Bracket; mill bottom and inside edges using high-speed steel face mill cutter and high-speed steel end mill: Material, cast iron; cutting speed, roughing, 80 ft. per min.; finishing, 120 ft. per min.; feed rate, roughing, 11 $3/4$ in. per min.; finishing, 9 $1/4$ in. per min.; depth of cut, $3/16$ in.; production, 2 pieces per hr.

## 4. MILLING MACHINES

**CLASSIFICATION AND USES.**—The types and sizes of milling machines are numerous and their designs merge into one another. It is, therefore, difficult to classify them. The following classification is based on general appearance or design.

**1. Knee and Column Type** is so called because the spindle is fixed in the column or main body, and the platen or table is capable of adjustment longitudinally, transversely, and vertically. Machines of this type are of rather universal application and generally

are selected for that class of production milling which involves relatively small parts, manufactured in limited quantities, with frequent set-ups. They also are used in tool room work and in jobbing shops.

These machines can be equipped with fixtures and multi-spindle attachments to permit their use as production units. Such procedure pays in many shops, where certain jobs are manufactured in sufficient quantities to justify a knee and column type machine for high production, with the idea that it easily can be stripped of its high-production elements and put back on regular run of work.

Knee and column machines are subdivided as follows:

*a*. *Plain Horizontal*, with spindle located horizontally.

*b*. *Universal*, equipped with a swiveling table, for the cutting of helical grooves.

*c*. *Vertical*, with the spindle located vertically.

*d*. *Automatic*, which combines the advantages of the bed type and the knee and column type millers.

**2. Hand Millers** usually are small machines of the knee and column type, in which the feeding movement of the table is controlled by hand. They are used in the manufacture of comparatively small quantities of light parts. Hand millers are subdivided as follows: *a*. Floor type. *b*. Bench type. The latter are used for the machining operations of very light work.

**3. Fixed Bed Type** machines are intended for use in the manufacture of parts in large quantities, and for this reason they are more rigidly built and simpler than the knee and column type millers. These machines are built on the plan of standard unit construction, which permits the make-up, from standard and complementary units, of a great variety of spindle combinations and feed cycles to meet the specific requirements of manufacture of a given product. See Figs. 15 to 22.

Fixed bed machines often are called semi-automatic, because, with proper fixtures,

| | | 1 | Shell end-mill | 2 1/4 | High-speed steel | 111 | 66 | 8 | 0.0072 | 1/8 |

the work may be clamped and the machine started through a definite automatic cycle, such as rapid advance of work to cutter, cutting feed, rapid return to the starting position, and stop. These machines are subdivided as follows: *a.* Plain (single spindle); *b.* Duplex; *c.* Multiple spindle; rail; bridge; special types.

4. **Rotary and Drum Type Millers** are provided with fixtures and are used for mass production work in which the cutting is continuous, with no idle time. The parts are loaded on one side of the machine, pass first the roughing, and then the finishing cutters, and return to the loading position, where they are replaced. Drum type machines derive their name from the fact that the parts to be milled are mounted on a drum-like fixture which rotates continuously.

5. **Planetary Milling Machines** are used to mill plain or formed internal surfaces. The cutter is inserted in the bore to be milled and, while rotating, is fed to depth radially, makes a single sweeping cut about the bore, and is withdrawn first radially, then axially.

6. **Thread Milling Machines** are designed to cut threads and worms. In these operations milling cutters are used rather than single-point cutting tools.

7. **Die-sinking and Profiling Machines** are designed to reproduce accurately forms and contours from a master by means of a tracer, contact with which maintains the master form throughout the operation, thus controlling the relative position of work and cutter. These machines are subdivided into:

*a.* Hand controlled, in which the tracer is guided by hand over the master form.

*b.* Automatic, where the tracer, once the cycle is started, follows automatically the master form without requiring the assistance of the operator.

**MILLING MACHINE ATTACHMENTS.**—The range of work that a milling machine can do is greatly increased by the use of attachments. An almost endless variety of attachments has been devised for special requirements. Many of these attachments, however, have become standard equipment units of the milling machine. Among these the most important are the following: 1. Universal dividing head. 2. Index head. 3. Heavy vertical milling attachment. 4. Circular milling attachment. 5. Universal spiral milling attachment. 6. Slotting attachment. 7. Rack milling attachment. 8. Standard index base. 9. Cam milling attachment. 10. Toolmaker's vise.

# DRILLS AND DRILLING*

## 1. DRILLING PRACTICE

**CONSTANT FOR FINDING SPEEDS OF DRILLS.** (See Table 1.)—For finding the speed in feet when the number of revolutions is given, or the number of revolutions, when the speed in feet is given.

Constant = 12 ÷ (size of drill × 3.1416).
Number of revolutions = Constant × speed in feet.
Speed in feet = Number of revolutions ÷ constant.

**Table 1.—Constants for Drill Speeds**

| Size of Drill, in. | Constant | Size of Drill, in. | Constant | Size of Drill, in. | Constant | Size of Drill, in. | Constant | Size of Drill, in. | Constant |
|---|---|---|---|---|---|---|---|---|---|
| 1/8 | 30.55 | 3/4 | 5.09 | 1 3/8 | 2.78 | 2 | 1.91 | 2 5/8 | 1.45 |
| 3/16 | 20.38 | 13/16 | 4.70 | 1 7/16 | 2.66 | 2 1/16 | 1.85 | 2 11/16 | 1.42 |
| 1/4 | 15.28 | 7/8 | 4.36 | 1 1/2 | 2.55 | 2 1/8 | 1.80 | 2 3/4 | 1.39 |
| 5/16 | 12.22 | 15/16 | 4.07 | 1 9/16 | 2.44 | 2 3/16 | 1.75 | 2 13/16 | 1.36 |
| 3/8 | 10.19 | 1 | 3.82 | 1 5/8 | 2.35 | 2 1/4 | 1.70 | 2 7/8 | 1.33 |
| 7/16 | 8.73 | 1 1/16 | 3.59 | 1 11/16 | 2.26 | 2 5/16 | 1.65 | 2 15/16 | 1.30 |
| 1/2 | 7.64 | 1 1/8 | 3.39 | 1 3/4 | 2.18 | 2 3/8 | 1.61 | 3 | 1.27 |
| 9/16 | 6.79 | 1 3/16 | 3.22 | 1 13/16 | 2.11 | 2 7/16 | 1.57 | 3 1/16 | 1.25 |
| 5/8 | 6.11 | 1 1/4 | 3.06 | 1 7/8 | 2.04 | 2 1/2 | 1.53 | 3 1/8 | 1.22 |
| 11/16 | 5.56 | 1 5/16 | 2.91 | 1 15/16 | 1.97 | 2 9/16 | 1.49 | 3 1/4 | 1.18 |

**DRILL SPEEDS.**—The correct speed of drill will vary with the composition and hardness of the material, type of machine used, depth of hole, lubricant, and other conditions. The speed and feed to be used for any particular job is largely a matter of judgment and trial. The Cleveland Twist Drill Co. recommends the speeds given in Table 2 as a basis for good practice with high-speed steel drills. Speed of carbon steel drills should be from 40 to 50% of the speed of high-speed steel drills.

---

* Staff contribution.

While an occasional drill will withstand for days a cutting speed of 150 ft. per minute, in either cast iron or steel (the latter under a lubricant), it rarely is expedient to drive any but very small ones faster than 100 ft. per min. Operating drills at an excessive speed usually is expensive, and it is more economical to err in the other direction. Table 3 gives the speeds and feeds recommended by the Cincinnati-Bickford Tool Co. as representative of good commercial drilling practice. The table is based on cutting speeds of 100 ft. per min. in cast iron, 80 ft. per min. in medium steel, and 40 to 60 ft. per min. in unusually hard steel.

**DRILL FEEDS.**—The rate at which a drill may be advanced per revolution depends on the toughness of the material to be drilled, the ability of the machine to resist thrust without forfeiture of alignment and upon the knowledge that is exercised in the grinding of the drill—the size of its included angle, the width of its chisel point, and the keenness and evenness of its cutting edges, all being deciding factors. Were it not for the weakening effect upon the drill it could be said that the stiffer the machine, the less the included angle, the narrower the chisel point, the smaller the degree of the spiral, the greater the uniformity of the cutting lips and the more efficacious the lubricant in minimizing the frictional resistance of the chips, the coarser becomes the feed it is permissible to use. But, inasmuch as the durability of the drill must not be impaired, the advantage obtainable through the application of these axioms has its limitations.

The size of the drill and the material drilled govern, in practice, the feed used. A general rule is a feed of 0.001 to 0.002 in. per revolution for drills smaller than 1/8 in., 0.002 to 0.004 in. per revolution for drills 1/8 to 1/4 in., 0.004 to 0.007 in. per revolution for drills 1/4 to 1/2 in., 0.007 to 0.015 in. per revolution for drills 1/2 to 1 in., and 0.015 to

**Table 2.—Drill Speeds for Various Materials**

| Material | Speed, ft. per min. | Material | Speed, ft. per min. |
|---|---|---|---|
| Mild machinery steel, 0.2–0.3 carbon | 80–110 | Malleable iron | 80– 90 |
| Steel 0.4–0.5 carbon | 70– 80 | Ordinary brass and bronze | 200–300 |
| Tool steel 1.2 carbon | 50– 60 | High tensile bronze | 70–150 |
| Steel forgings | 50– 60 | Monel metal | 40– 50 |
| Alloy steel | 50– 70 | Slate, marble and stone | 15– 25 |
| Stainless steel | 30– 40 | Aluminum and its alloys | 200–300 |
| Soft cast iron | 100–150 | Magnesium and its alloys | 250–400 |
| Hard chilled cast iron | 70–100 | Bakelite | 100–150 |
| | | Wood | 300–400 |

| 3 | 125 | .030–.050 | 3 3/4–6 1/4 | 100 | .020–.035 | 2–3 1/2 | 50–75 | .012–.020 | 3/4–1 1/2 |

0.025 in. per revolution for drills larger than 1 in. These figures apply to medium steel. Alloy steel and hard steel usually require lighter feeds than the foregoing while cast iron, brass and aluminum may be drilled with heavier feeds. See Table 3.

**DRILLING LUBRICANTS.**—To obtain the maximum performance from drills operating in any material except cast iron, a copious supply of cutting lubricant at the cutting edges is necessary. Cast iron should be drilled dry, or with a jet of compressed air directed into the hole to act as a cooling medium.* The following lubricants are recommended by the Cleveland Twist Drill Co. for cutting other materials, the preference being in the order given:

**Hard and Refractory Steel.**—Turpentine, kerosene, and soluble oil.

**Soft Steel.**—Lard oil, soluble oil.

**Wrought Iron.**—Lard oil, soluble oil.

**Malleable Iron.**—Soluble oil.

**Brass.**—Paraffin oil, or dry.

**Aluminum and Soft Alloys.**—Kerosene, soluble oil.

See also Boston and Oxford's experiments on cutting fluids, p. 21–51.

**PROPORTIONS OF TWIST DRILLS.**—Table 4 shows the dimensions of twist drills as given by standard B 5.0–1936 of the A.S.A. Fig. 1 illustrates nomenclature adopted by the A.S.A. in the same standard for twist drills. This standard covers only straight shank drills. The standards of various manufacturers differ in regard to taper shank drills. For dimensions of the various drill tapers in common use, see pp. 12–17 to 12–23.

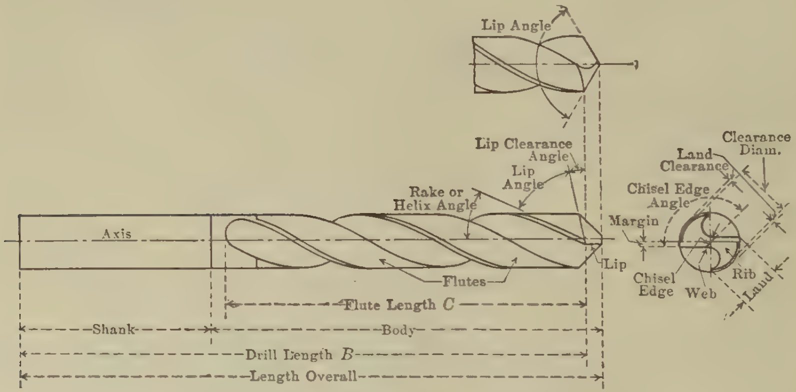

FIG. 1. Standard Straight Shank Twist Drill

For maximum efficiency it is essential that the point of the drill be properly ground. For iron and steel, experience indicates that a lip angle of 108 deg., *i.e.*, each lip making an angle of 59 deg. with the axis of the drill, gives the most efficient performance. The best lip clearance angle seems to be 12 deg. at the periphery of the drill, increasing gradually as the center of the drill is approached. The chisel-edge angle should be approximately 135 deg. Insufficient lip clearance angle at the center of the drill is the principal cause of drills splitting in the web. It also is essential that the cutting edges be of equal length.

**TWIST DRILL AND STEEL WIRE GAGES.**—Three standards of gages for twist drills and steel wire are in use—the Manufacturers' Standard, used by the Morse Twist Drill Co., Brown & Sharpe, and other manufacturers, the Stubs gage, and that of the Standard Tool Co. The Stubs and Manufacturers' gages are given in the table on page 6–25. The Standard Tool Co. gage agrees with the Manufacturers' gage for sizes from Nos. 1 to 60, inclusive, and with the Stubs gage for sizes from Nos. 61 to 80. In addition it has additional $^1/_2$ sizes interpolated at Nos. 60 $^1/_2$, 68 $^1/_2$, 69 $^1/_2$, 71 $^1/_2$, 73 $^1/_2$, 74 $^1/_2$, 78 $^1/_2$, and 79 $^1/_2$.

**DRILL GRINDING.**—Improper performance of drills, drill breakage and excessive power required for drilling usually can be traced to improper grinding of the drill. Correct grinding of drills by hand is almost impossible, and machine grinding will pay for itself even in the smallest of machine shops. It is essential not only that the lips be ground at the proper angle, but also that they be of equal length and that clearance should be properly ground. The web of the drill should be thinned down as the drill is worn away in order to provide the proper thickness of web and the correct angle and thickness of the chisel point. Drill grinding and point thinning machines are made by Wm. Sellers & Co., Philadelphia.

---

* Boston and Oxford's experiments indicate that a cutting fluid will improve performance in drilling cast iron. See p. 21–51.

**POWER REQUIRED TO DRIVE DRILLS.**—The Cincinnati-Bickford Tool Co. gives the following formulas for the horsepower required for drilling cast iron and steel with high-speed steel drills. In these formulas $D$ = diam. of drill, in.; $F$ = feed, in. per revolution; $N$ = rev. per min.

Cast iron Hp. = $0.404\,D^2FN$ . . . . . . . . . . . [1]

Mild steel Hp. = $0.98\,D^2FN$ . . . . . . . . . . [2]

These formulas are based on the use of properly-ground drills, and on the use of a soda-water coolant when drilling steel. Under other conditions the horsepower will considerably exceed the values given by the formulas.

Table 5 gives the results of tests made by the American Tool Works Co., Cincinnati,
